# STUDIES IN THE GENETICS AND CYTOLOGY OF TWO SPECIES IN THE GENUS ASTER AND THEIR POLYMORPHY IN NATURE <sup>1</sup>

Ralph H. Wetmore and Albert L. Delisle

THE FOLLOWING genetical and cytological studies were made in conjunction with investigations in relative growth and morphogenesis (Delisle, 1938) in two species of Aster, A. novae-angliae L., A. multiflorus Ait.2 and their hybrid. Certain aspects of this work appear significant when considered in relation to the polymorphy of these species and possibly have a bearing on the recognized polymorphy in the genus. A. novae-angliae is tall, hairy, stout, and relatively unbranched in the young stages, becoming corymbed only at the summit later. It has numerous large, soft, minutely pubescent, lanceolate, acute, entire leaves which are provided with marked auriculations at the base. The bracts of the involucre are loose, erect, nearly equal, glandular-viscid and linear; the heads are characteristically solitary on individual branchlets; the rays of the type species are violet-purple and those of the forms roseus (Desf.) Britton and geneseensis House are rose and white, respectively. This species flowers from August to October, with the bulk of the plants blooming in September.

A. multiflorus is a somewhat shorter, very much more branched (Delisle, 1937) and bushy, short-pubescent plant with crowded heads on the spreading, racemose branches. The leaves are crowded, linear, entire, sessile, non-auriculate, spreading, and rigid, with rough or ciliate margins, passing above into the spatulate, obtuse, ciliate bracts of

<sup>1</sup> Received for publication September 6, 1938.

This is one of a series of studies on the genera Aster and Solidago which were begun when the senior author was a National Research Fellow in the Biological Sciences. To the Council he expresses his gratitude for their support at that time.

<sup>2</sup>The name A. multiflorus is used here because of its general occurrence in Gray's Manual, 7th edition, and other floras, instead of A. cricoides, which, according to Mackenzie, antedates it and under which the original description was made. (Mackenzie, 1926; Blake, 1930.)

the inflorescence; the involucral bracts are hairy and have squarrose or spreading tips; the rays are white on numerous, small, crowded, racemose heads. Flowering occurs from August to October. A comparison of some of the characters of this species is made with those of A. novae-angliae in table 1.

The hybrid between the two species is intermediate in many characters, upright, much branched, but not bushy, puberulent to hirsute, but not glandular, with soft leaves and involucral bracts merely spreading at the tip. It flowers slightly later,

mostly in September to October.

Figure 1a indicates the relative size of the heads in A. novae-angliae and A. multiflorus. In this figure are shown also the contrastive sizes and numbers of rays in the capitulum of each species. The contrast of achene shape and size is evident from figure 1b. Figure 2 illustrates the nature of leaves and branches in the two species of Aster and their hybrid.

Concurrently with the genetical study of these two species of Aster, a cytological investigation of the same material was undertaken. It included studies in the number, morphology, and behavior of the chromosomes during mitotic and meiotic divisions (the pollen mother cells) in these species, their varieties, their reciprocal hybrids, the back crosses, and plants of the  $F_2$  generation. Investigations were carried out on field material whenever available. The study also included an ecological variant, a forma depressa of A. multiflorus.

MATERIALS AND METHODS.—Test experiments carried out on many plants of these two species over a period of years proved them to be self-sterile. Repeated controlled pollinations from the same plant have consistently failed to produce achenes.<sup>3</sup> The

<sup>3</sup> The flower-heads of all the plants used were carefully bagged previous and subsequent to anthesis in order to eliminate all sources of contamination. The pollen in all

M represents an achene of A. multiflorus; N, A. novae-angliae;  $N \times M$  and  $M \times N$ , achenes which will produce the reciprocal  $F_1$ -hybrids;  $F_1$ , achene produced by the  $F_1$ -hybrid when inbred ( $\times 4.2$ ).

[The Journal for December (25: 727-816) was issued January 11, 1939.]

American Journal of Botany, Vol. 26, No. 1, January, 1939.

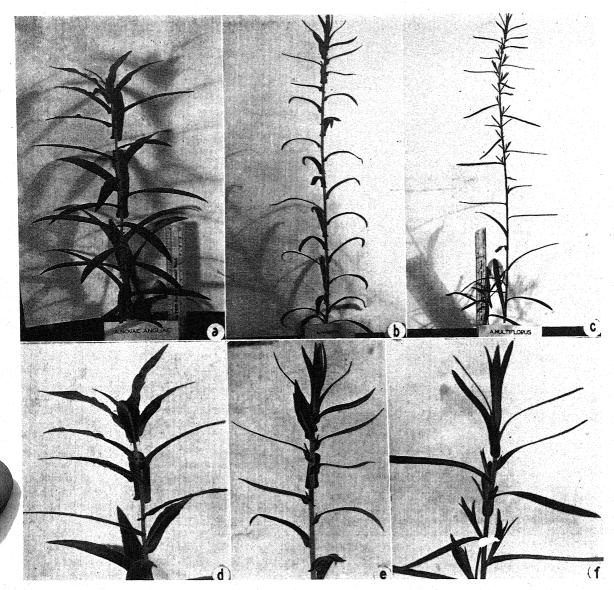

Fig. 2. Morphological comparison of A. novae-angliae (a and d), A. multiflorus (c and f), and their hybrid A. novae-angliae  $Q \times A$ . multiflorus  $\mathcal{E}$ , (b and e). Note differences in branching, auriculation, size of leaf, etc.

breeding experiments reported here are based on the typical A. novae-angliae, with violet-purple rays, and its two forms roseus and geneseensis with rose and white rays, respectively, and the manyflowered white aster, A. multiflorus. The original cases was obtained from bagged flower-heads, transferred on the sterilized blade of a fine iridectomy scalpel, and gently rubbed on the inner surface of the bipartite stigma. Since the marginal ligulate flowers are pistillate, and since anthesis proceeds centripetally in the flower heads of the species, the female ray florets proved more accessible for manipulation and more desirable for contro ed pollina-tion than the centrally located and perfect disc florets. Fertilization must have been effected more frequently in the ray florets, as those produced the largest number of achenes. All achenes were germinated in Petri dishes lined with moist filter paper at room temperature, and the seedlings were transferred to individual small pots in the greenhouse to ensure absolute identity.

material was collected in the field and inbre or two or more generations. Taxonomically these two species of Aster are regarded as being closely related. Genetical are refertile and cross readily with the cross A. novae-ang that the cross A. novae-ang that the cross A. novae-ang that the cross are different several and red achieves were obtained which produced health a dingr. Seventy-fix per cent of these were flower in the sarry year.

The reci tempted, u.

A. mu. florus ways a collected in Combides on wester

4 These were so collected in Cambridge on waste ground behing. It man Ir mary. The forms geneseensie was cotained from achenes produced on he pollinated plants of the white-flowered form a owing the Marvard Bot nic Gardens.

erably less success. Repeated pollinations, however, have produced approximately one hundred achenes, which germinated badly and produced seedlings which are greatly retarded, look somewhat abnormal, and remain in the rosette condition for a longer time (fig. 3b).

Since the interfertility of the  $F_1$  plants is fairly high, there is no difficulty in obtaining achenes for plants of the  $F_2$  generation. Both back-crosses

were also obtained without difficulty.

In the cytological studies, capitula of the proper stage of development were fixed in acetic-alcohol—30 per cent glacial acetic acid and 70 per cent absolute alcohol—and transferred to 85 per cent alcohol, there to remain until examined. Smearing techniques were found not too satisfactory because of the small size of the chromosomes. Resort was therefore made to embedding and sectioning in celloidin (Jeffrey, 1928) according to the technique and schedule outlined by one of the authors (Wetmore, 1932).

Observations.— $F_1$  plants produced from these crosses are generally intermediate in character between the two parents. The stem leaves are distinctly clasping at their bases and are provided with auriculations, as are those of A. novae-angliae. The plants vary in height from 0.45-1.7 m. (table 1).

The hybrid has the characteristic type of glandular pubescence of A. novae-angliae, though the glands are less frequent (see table 1). Breeding experiments have shown the ray color in the type species A. novae-angliae and its two forms to be genetically distinct. When purple-rayed plants are pollinated with pollen from other purple-rayed plants, only purple-rayed individuals are produced; the white-rayed form, when pollinated from whiterayed types, yields only plants with white rays. Further controlled crosses involving the purplerayed and the white-rayed forms have yielded only purple-rayed heads illistinguishable from the type plant and suggesting a complete dominance of color over the albino. The rose-colored form is not so simply interpreted. Further work is necessary before the results obtained can be understood.

The hybrids produced from a cross between A. nover-angliae  $\mathcal{P}$  type with purple rays  $\mathcal{L}$   $\mathcal{L}$   $\mathcal{L}$   $\mathcal{L}$  have clear bluish-violet rays. Crosses involving A. novae-angliae forma roseus  $\mathcal{L}$   $\mathcal{L}$ 

As previously pointed out, the syprids resulting from the cross A multinorunt  $\times$  A. novae-angliae of are greatly retarded. It will be noted that the rosette leave derities in development and in general angles of being

figure are exactly the same ago yorids in this figure are exactly the same ago yorids in this under the same greenhour condain. These hydrogeneous seedlings are not only retarded in their declepment, but are markedly smaller than the

reciprocals of the same age. They possess small cotyledons like those of their female parent, as shown in table 1. Comparable results were obtained in mice by Castle (1936) and in Triton by Pariser (1936).

Table 1 and figure 1b give the relative sizes of the achenes from which these reciprocal hybrids germinated. It will be noted that the differences

Fig. 3. Comparison of reciprocal hybrids of the same age, grown under identical green house conditions. (a) A. novae-angliae  $\mathcal{Q} \times A$ . multiflorus  $\mathcal{Q}$  and (b) A. multiflorus  $\mathcal{Q} \times A$ . novae-angliae  $\mathcal{J}$ .

in sizes of the reciprocal hybrid seedlings (as measured by size of cotyledons) are correlated with differences in the sizes of the achenes (fig. 1b) in inbred A. novae-angliae and A. multiflorus, in A. novae-angliae \( \frac{2}{3} \text{ A. multiflorus } \frac{2}{3} \), and in the reciprocal cross. The different sizes of the two achenes producing the reciprocal hybrids seem to be correlated with the size of the achene in the maternal parent (Delisle, 1938). It was also noticed that the smaller achenes in these two inbred species tended to produce smaller seedlings. As was found in rice by Ramaswami (1935), these early differences gradually even out as the plants get older. The variability of the mature plants of the F<sub>1</sub> generation is relatively slight.

Plants of the  $F_2$  generation show greater variability (fig. 4) than those of the  $F_1$  hybrids. The majority of these  $F_2$  plants, however, show a tendency to approximate in morphological characters the appearance of A. novae-angliae rather than that of A. multiflerus.

The synthetic hybrid between A. novae-angliae ? and A. multiflorus of here reported is identical with A. amethystinus Nutt (of Gray's Manual). Ever

<sup>5</sup> It is to be noted that the cotyledons in this hybrid were consistently larger than those of even the maternal parent.

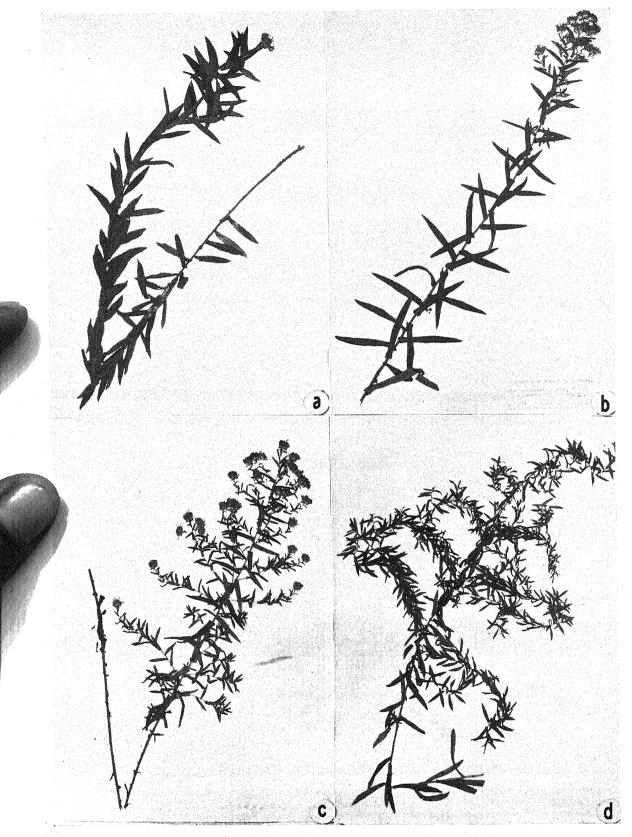

Fig. 4. Phenotypes of the F2 generation. Note variability.

Stem	Stout, glandular-pubescent, especially above, less glandular below; high (0.5-2.5 m.).	Pale or hoary, slender with minute, close to hirsute pubescence. Usually low (0.3-1.0 m.).	Intermediate in habit, puberu- lent, slightly glandular, inter- mediate in height (0.45-1.7 m.).
Degree of branching	Unbranched when young, be- coming corymbed at summit later, upright.	Very much branched and bushy.	Upright, intermediate in branching, not bushy.
Branchlets	Viscid-glandular-pubescent, non-wiry.	Conspicuously pubescent with appressed hairs, pale or hoary, wiry.	Cinereous-pubescent, with spreading, non-glandular hairs, non-wiry.
Rhizome	Perennial and spreading.	Perennial and spreading.	Perennial and spreading.
Habitat	Moist, chiefly calcareous grounds.	Dry, sandy soil.	Moist ground.
Time of flowering	August-October.	August-October.	(August) September-October.

<sup>\*</sup> All measurements except height of plants based on data obtained from samples of 100 or more.

since A. amethystinus was first described in 1840 by Thomas Nuttall, reports of its sporadic occurrence have been presented. Since it is repeatedly mentioned that, when found, it grows close to A. novae-angliae and A. multiflorus, it has generally

<sup>6</sup> There are at the Gray Herbarium approximately twenty-five specimens and at the New England Botanical Club Herbarium thirteen specimens of this hybrid. Figure 5 indicates the distribution of A. novae-angliae, A. multiflorus, and A. amethystinus in the United States and adjacent Canada based on material available at the Gray Herbarium.

been suspected that A. amethystinus represented a natural cross between these species (Benke, 1930; Knowlton, 1930). Figure 5 shows that in all cases A. amethystinus occurs where the ranges of A. novae-angliae and A. multiflorus overlap.

Although hybridism has long been supposed, as far as the writers know, no positive proof through breeding experiment has been published as yet concerning the parentage of this species.<sup>7</sup>

 $^7$  In a personal letter to the senior author, Prof. A. J. Eames reported having pollinated plants of A. multi-

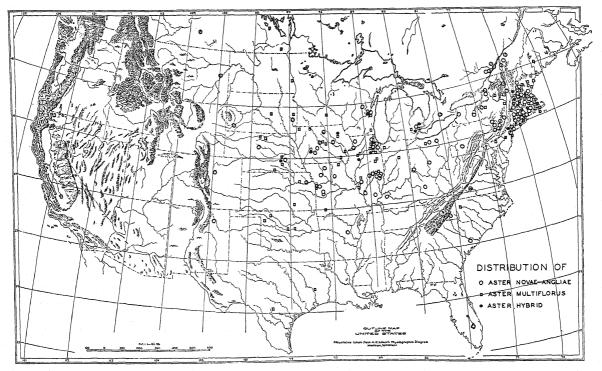

Fig. 5. Comparative distribution of A. novae-angliae, A. multiflorus, and their F<sub>1</sub>, A. amethystinus, in the United States. (Gray Herbarium Collection.)

In the fall of 1933 the writers collected a specimen with rose rays which was identified as A. amethystinus. In this case again the plant grew among many plants of A. multiflorus and within a short distance of a few plants of A. novae-angliae. It is of interest to point out that this A. amethystinus-like florus with pollen from A. novae-angliae and obtaining seed which germinated into the typical A. amethystinus. It is interesting to note that Eames seems to have had no serious difficulty in germinating seeds of this cross nor in having them flower the first year. This is in striking contrast to the results of the present work.

<sup>8</sup>This plant was found at Gerry's Landing on the Charles River, in Cambridge, Massachusetts. The speci-

men is now at the Gray Herbarium.

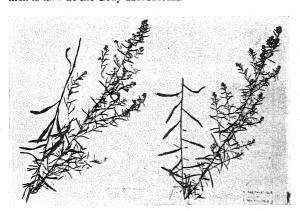

Fig. 6. Comparison of synthetic backcross of  $F_1 \circlearrowleft \times A$ . multiflorus Q (right) and specimen found in nature (left).

plant collected in Cambridge, Massachusetts, was seemingly resynthesized in the greenhouses simply by back-crossing the synthetic  $F_1$  hybrid with A. multiflorus (fig. 6, right). The resulting plant checked in all morphological characters with the specimen found in nature, as shown in figure 6 (left), and provisionally identified as A. amethystinus.

A study of these two species and of A. amethystinus in nature shows a great variability of forms. A graded series could almost be provided from one parent, through the hybrid, to the other parent. A study of herbarium material indicates the same polymorphy, apparently perplexing to the taxonomist, for forms belonging to this complex have been given different names. In breeding experiments, the writers found it possible to duplicate this range of perplexing forms, producing experimentally replicas of many of the problem plants of the taxonomist. A large number of these plants proved to be back-crosses here just as they did in Tradescantia and Iris, extensively studied by Anderson (1936), and in Solidago (Goodwin, 1937).

In order to compare laboratory material with field material, one usually makes use of qualitative taxonomic characters. A method devised by Anderson (1936) permits one to translate these qualitative characters into numerical values. Frequency distributions can then be made of whole populations on a sliding scale whose ends represent the two parent species and whose center, the hybrid. Thus when carefully selected morphological characters are to the selected morphological characters.

	Total index values	14	100	0

<sup>&</sup>lt;sup>a</sup> The white form is so rare as to be insignificant or negligible in this study.

acters are given numerical values, it is possible to assign each individual plant a position in the scale. Table 2 lists six contrasting morphological characters given weighted arbitrary values and chosen not only because they are of significant nature, but also because of the ease in scoring. In figures 7 and 8 appear histograms indicating the results of this method of scoring when applied to controlled genetical crosses and to field and herbarium material. The index values are plotted on a basal scale ranging from 0 (plants possessing all the characters of pure A. multiflorus) to 14 (plants possessing all the characters of the species A. novae-angliae).

These histograms show that many individuals are found in nature which are neither hybrids nor pure species. They possess morphological characters ranging from those of the hybrid to those of either parent. They are usually the perplexing forms, which have even been assigned varietal rank. The majority of these, it seems, are really the product of promiscuous back-crossing of hybrids with the

parental species. It should be mentioned that an attempted analysis of the individual characters upon which these histograms are based gives no indication of simple Mendelian segregations. Rather the ratios are complex and not at present understood. Nor are there evidences of linkage in the six characters involved. Further work must be done before any understanding of the genetic relations of these characters can be admitted.

Both A. novae-angliae and A. multiflorus prove to have 5 chromosomes as a haploid count. This number was obtained from an investigation of the pollen mother cells (Pl. 1, fig. 1, 4). Many somatic counts of 10 were seen in the nucellus, in the integuments of the ovule and in the staminal tissues of each species (Pl. 1, fig. 3). These findings confirm Carano's (1921) report of 5 chromosomes for the embryo sac of A. novae-angliae.

In A. novae-angliae there is considerable difference in chromosome size, the size-ratio of the largest to the smallest chromosome at metaphase in the

A. multiflorus, metaphase, equatorial view.—Fig. 6. A. multiflorus, forma depressa, metaphase, n=5.—Fig. 7. Reductional metaphase in F<sub>1</sub>.—Fig. 8. Diakinesis in F<sub>1</sub>.—Fig. 9. Diakinesis in F<sub>1</sub>. Note presence of univalents and bivalents and inequality of homologues in two smaller pairs of bivalents.—Fig. 10. Somatic

first meiotic division being approximately 3.5:1. There appear three large chromosomes, one medium-sized and one very small. Correspondingly, dividing somatic cells exhibit six large, two medium-sized, and two small chromosomes. The first meiotic division proceeds with much regularity as is indicated in the illustrations of prophase (pl. 1, fig. 2) and metaphase (pl. 1, fig. 2a). It is always possible to distinguish the smallest and largest pairs by their size. The medium-sized chromosome pairs can usually be so identified.

A cytological investigation of the forms roseus and geneseensis of this species has shown no detectable difference in chromosome number, size, and morphology from the condition existing in the type, A. novae-angliae. In meiosis all have been found to possess five pairs of chromosomes which behave regularly, produce viable pollen and abundant seed. The diploid (2N) number of chromosomes in dividing cells of the nucellar tissue is again found to be ten.

A study of meiosis in the P.M.C.'s of A. multiflorus has indicated much regularity in the behavior
of all five pairs of chromosomes. Figures 4 and 5
(pl. 1) show two views of a first division metaphase
plate with five pairs of chromosomes visible at the
equator. Studies in chromosome morphology in this
species indicate differences in the sizes of the chromosomes in this species. There is one large chromosome, two medium-sized, and two smaller ones, with
an approximate size ratio of 2.5:1 between the
largest and the smallest in metaphase view (pl. 1,
fig. 4). All chromosomes are considerably smaller
than those of the corresponding size class in A.
novae-angliae.

A sea-side form of A. multiflorus marked by a distinct prostrate habit was examined cytologically and the genoms found to be indistinguishable from the type with five pairs of chromosomes as shown in figure 6.

As previously indicated, crosses involving the two species are effected with ease. An outstanding characteristic of the  $F_1$  hybrids of A. novae-angliae  $\mathcal{P} \times A$ . multiflorus  $\mathcal{F}$  is their comparatively high fertility. As a result there is no difficulty in obtaining plants of the  $F_2$  generation. Figure 7

<sup>9</sup> This plant, collected at Montauk, Long Island, New York, because of its extreme prostrate habit, has been transferred to and grown under greenhouse conditions for more than two years without any noticeable change in growth-form. Such a comparable coastal ecotype has been described by Turesson (1922) in Atriplex.

metaphase in nucellar tissue of reciprocal hybrid (A. novae-angliae 3).—Fig. 11. Diakinesis in F2.—Fig. 12. Diakinesis in F1  $\mathcal{Q} \times A$ . novae-angliae 3.—Fig. 13. Diakinesis in F1  $\mathcal{Q} \times A$ . multiflorus 3.—Fig. 14. Metaphase in F1  $\mathcal{Q} \times A$ . multiflorus 3.—Fig. 15. Diakinesis in A. amethystinus-like plant.—Fig. 16. A. novae-angliae, P.M.C. showing ten pairs of chromosomes.—Fig. 17. A. novae-angliae, somatic cell from nucellus showing twenty chromosomes.—Fig. 18. A. novae-angliae, anaphase, first division of the 3 gametophyte, showing ten chromosomes in each daughter cell.

(pl. 1), shows a reductional metaphase of the F<sub>1</sub> hybrid and indicates comparative sizes of the chromosomes with respect to the parental genoms (figs. 1, 4). It is to be noted that in homologous pairs the larger chromosome from the A. novae-angliae parent can usually be distinguished at diakinesis (pl. 1, fig. 9). It is interesting also that the total diameter of the plate at metaphase is intermediate between those of corresponding plates in the parental species. Figure 8 is that of a diakinesis with five pairs of chromosomes, by far the most frequent type; figure 9 shows a diakinesis with four bivalents and two univalents. The latter occurs in approximately 23 per cent of the cells examined. The rest are apparently normal.

Morphologically these plants<sup>10</sup> are intermediate in character between their two parents. The affinity between the chromosomes of the two species is fairly strong in the four larger pairs of chromosomes and weakest in the smallest unequal pair, the members of which tend occasionally to dissociate or fail to pair altogether.

The abundance of plants of the  $F_2$  generation has provided ample material for a study of the meiotic process in these plants. A selection of buds from distinct phenotypes (fig. 4) in the  $F_2$  generation has indicated appreciable pollen sterility and some irregularity in meiosis. Figure 11 (pl. 1) indicates four bivalents and two univalents in one of the diakineses, suggesting a premature separation of partners or absence of pairing due to a lack of complete homology between the partners. As shown in figure 4, the variability of these  $F_2$  plants is greater than that of the  $F_1$ .

Figures 12 to 14 (pl. 1) represent diakineses and metaphase plates in the reciprocal back-crosses of the  $F_1$  plants with the parents. Table 3 indicates approximately the relative amount of pollen sterility<sup>11</sup> and the frequency of bivalents and univalents in these back-crosses. Figure 15 shows a diakinesis in a plant collected in the field and suspected of being a natural back-cross of an  $F_1$  plant with A. multiflorus. From breeding experiments this plant has been shown (fig. 9) to be a natural back-cross of an  $F_1$  hybrid with A. multiflorus.

The two species of Aster, A. novae-angliae and A. multiflorus and their forms and A. subulatus (Wetmore, in ed.) are the only Asters as yet reported possessing five pairs of chromosomes. This number is the lowest in a genus whose species preponderantly contain nine pairs of chromosomes or multiples of this number (Tahara and Shimotomai, 1926; Wetmore, in ed.). The chromosomes in the other reported species of the genus also show wide variation in size (Tahara and Shimotomai, 1926),

 $^{10}$  Due to the retarded condition of the reciprocal hybrids resulting from the cross A. multiflorus  $\mathbb{Q}\times A.$  novae-angliae  $\mathcal{E}$  and the relative scarcity of bud material, only a few plants have been brought to flower. Figure 10 shows a somatic mitosis (2N=10) in the nucellar tissue of the hybrid.

11 Those pollen grains of much smaller size than normal, with crushed walls and disorganized contents, were arbitrarily selected as being abnormal and sterile.

reaching their largest size in Aster Tripolium. There is also considerable range in chromosome size within the genom of each individual species.

During the investigation on chromosome behavior in Aster novae-angliae, one plant was found possessing tetraploid P.M.C.'s containing ten pairs of chromosomes (double the usual number), as shown in figure 16, in association with others with five pairs in the same loculus. Observations of dividing somatic nuclei in the nucellar and staminal tissues of this plant showed the occasional presence of giant tetraploid cells containing twenty somatic chromosomes (fig. 17). These are scattered heteroploid cells with the aberrant number of chromosomes and are not chromosomal chimeras of the sectorial or periclinal type (Ruttle, 1927). Figure 18 shows the first division of the gametophyte in a heteroploid microspore. It is not yet known how this tetraploidy came about in this plantwhether by temperature changes or by other means -(Peto, 1935, 1936; Sax, 1937). The capitula in which these heteroploid cells appeared were of larger size than those of the normal diploid plants of the same species. The plants, however, were not of larger size and showed no other external difference. A comparison of the cells of the leaf epidermis showed no difference in size from that of the normal diploid A. novae-angliae. It is of interest to note that somatic counts from root-tip smears gave only diploid numbers.

Discussion.—Breeding experiments in the production of controlled genetical crosses of two species of Aster have provided specimens which make possible the analysis of field and herbarium material. Thus, a single collection of an obvious intermediate plant (fig. 6) has been shown by means of breeding and by quantitative indices to be a natural backcross of the hybrid with one of its parents, A. multiflorus. This presupposes the existence of the natural hybrid at that locality at some earlier date and its subsequent back-crossing with A. multiflorus.

Distinct varietal hybrids can be produced from the crosses between the varieties of A. novae-angliae and A. multiflorus. The hybrid resulting from the form roseus of A. novae-angliae and A. multiflorus has rose-rayed heads and is otherwise indistinguishable from the blue-violet-rayed hybrids; it is similar in all respects to the spontaneous A. amethystinus f. leucerythros n. f. ligulis roseis (Bemis, 1930).

The parallel occurrence of five chromosome pairs in both A. novae-angliae and A. multiflorus, the general similarity of the genoms, and the degree of homology in their synaptic associations when these two species are crossed establishes a close cytological relationship between them. This is confirmed by the abundance of viable pollen and good seed produced in the  $F_1$  plants. In view of the general existence of five chromosomes (haploid) in these Asters and in view of the prevalence of higher chromosome numbers, 9, 18, 27, in other species of the genus, it is suggested that there are two chromosome series, a 5- and a 9-series, with 5 as a pos-

sible basic number in the genus. This difference in chromosome number therefore might well act as a genetic barrier to the production of viable hybrids between either of these two species of Aster with five pairs of chromosomes and any other species of the genus with nine or more pairs of chromosomes. No such hybrids are known to the authors. However, direct experimental testing of this suggestion has not yet been carried out.

It is of interest to note that five pairs of chromosomes constitute a basic number for Crepis (Hollingshead and Babcock, 1930). Lactuca exhibits an interesting similarity in chromosome number with the genus Aster, ranging from 5 in L. lanceolata (Tahara and Ishikawa, 1911), 9 in L. sativa (Gates and Rees, 1921) to 11-12 in L. Thunbergiana (Tahara and Ishikawa, 1911). Some other Compositae with five chromosomes are Picris hieracioides (Ishikawa, 1911), Melitella pusilla (Chiarugi, 1927), and Hypochaeris maculata (Tischler, 1928). Babcock and Cameron (1934) have shown that chromosome number and chromosome morphology are valuable taxonomic criteria in the genus Crepis. They concluded that the primary evolutionary process which has operated in the history of the genus has effected a transformation of 6- and 8-chromosome types from 10-chromosome ancestors. Other changes have come about by interspecific hybridization and amphidiploidy, polyploidy, and a concurrence of gene mutations. It is not yet known to what extent these phenomena have operated to produce the types with large chromosome number in the genus Aster. Further studies are intended in these directions.

Though much of the polymorphy in these species of Aster is referable to crossing in these plants, the possibility is not precluded that variation of a true hereditary nature within the species does occur, as was pointed out by Gregor et al. (1936) as a result of a study of experimental taxonomy in Plantago maritima. The color varieties of A. novae-angliae are examples. Since these two species are continuously cross-pollinated (being self-sterile), as is Aster anomalus described by Anderson (1928), there is reason to expect that some variation will appear in the progeny of such outbred plants. Those species which are continuously cross-pollinated will form new combinations in every generation, and the reappearance of distinctive combinations of characters from one generation to the next will tend to be a corollary of the degree of inbreeding. Turesson (1922) assigns the term "ecotype" to the "product arising as a result of genotypical response of an ecospecies to a particular habitat." It may well be that A. multiflorus is an ecospecies possessing ecotypes, such as the seaside prostrate form previously mentioned.

Genetical and field studies along with cytological investigations have shown the common occurrence in nature of hybrids such as A. amethystinus or such as Pentstemon neotaricus (Clausen, 1933). Clausen's studies, however, show this latter species

to be a natural true-breeding, amphidiploid hybrid between P. laetus and P. azureus. It is obvious that genetical experimentation aids in recognizing spontaneous hybrids in nature and opens up possibilities for the application of the experimental method in taxonomy (Müntzing, Tedin, and Turesson, 1931). The study of artificial or spontaneous hybrids between species or between biotypes within a species gives background for the interpretation of potential as well as actual polymorphy. It helps especially to understand why certain morphological characters are correlated in nature, through linkage or pleiotropy such as was shown by Clausen in Viola (1926) or through selective correlation as demonstrated by Tedin in Camelina (1925). Thus the puzzling variants between these two species of Aster, which present the double problem of origin and taxonomic classification can be relegated to the position of back-crosses or secondary hybrids one or more generations removed from the original cross between the species.

### SUMMARY

Genetical and cytological investigations in two species, forms, and their reciprocal hybrids in Aster afford an explanation for the polymorphic complex comprised of A. multiflorus Ait., A. novaeangliae L., and the natural gradations between them. Breeding experiments have provided plants which typify the polymorphy exhibited by this group in the field.

Utilizing a method by which qualitative characters are converted into quantitative numerical values, there was obtained confirmation of the genetical findings that these two species and their varieties hybridize extensively in nature. By this means there is produced a series of variable forms ranging in morphological and cytological characters from true hybrids, through back-crosses, to the type species. Thus there results a perplexing polymorphy, and forms belonging to the complex have been given different names by taxonomists.

Cytological investigations have indicated these two species of Aster possess a haploid chromosome complement of n = 5. A plausible explanation for the readiness of hybridization between these two species is found in the presence of similar genoms, each with five pairs of chromosomes. In the hybrid, these chromosomes exhibit remarkable affinity in the meiotic process and suggest a close phylogenetic relationship between the parents.

There are two chromosome groups in the Asters so far studied, a 5- and a 9-, with a polyploid series in the latter. The differences in chromosome number between these two groups, therefore, may act as a genetic barrier to the production of viable hybrids between the crossing of a species with five pairs of chromosomes and another species of the genus with nine or more pairs of chromosomes.

# THE EFFECT OF DROPS OF WATER ON LEAF TEMPERATURES 1

# Paul J. Kramer

Numerous investigations have been made of the temperature of leaves in relation to insolation, applications of various spray materials, the cooling effects of transpiration, and other factors. It appears, however, that no one has investigated the effects of drops or films of water on leaf temperatures. This is particularly surprising in view of the popular belief that leaves covered with drops of water can be seriously injured if exposed to the hot sun. Two explanations of such injury are commonly offered. One explanation is that drops of water on the leaves act as lenses, concentrating the sun's rays on the leaves and overheating the tissue. The other explanation is that the films and drops of water on the leaves decrease or stop transpiration, and the leaves, deprived of its cooling effect, become too hot. Such injury is supposed to occur when the sun shines brightly immediately after a summer shower or when plants exposed to the sun are sprinkled during the middle of the day.

Injury caused by sprinkling plants which are exposed to the hot sun apparently is much less common than ordinarily is supposed. Several botanists have told the writer that they believe such injury occurs, but considerable inquiry has failed to reveal specific examples known to have been caused in this manner. Although our botanical greenhouses, containing a wide variety of plants, are sprinkled regularly in the hottest part of the day during the summer, no damage has ever resulted. It seemed worth while, therefore, to determine the actual effect of drops and films of water The plants used were on leaf temperatures. African violet (Saintpaulia ionantha Wendl.), bryophyllum, camellia, geranium (Pelargonium), sedum, and yellow poplar. All plants were growing in pots except the camellia, which was growing in soil outside a laboratory window.

The leaf temperatures were measured by means of copper-constantan thermocouples connected through switches to a potentiometer and galvanom-

<sup>1</sup> Received for publication November 9, 1938.

eter. A junction was inserted in each side of a leaf blade and brought into close contact with the lower surface. The sedum leaves were thick enough to permit insertion of the thermocouples into the mesophyll tissue. Because of the small size of the leaves, the two thermocouples were inserted into separate leaves of sedum and African violet. In some experiments the plants were exposed to the sun, but a number of experiments were performed in the laboratory under a 500 watt mazda lamp equipped with a reflector. Variations in light intensity and especially in air movement caused rapid fluctuations in temperature out-of-doors. The procedure and the results were similar in the two experiments. After readings had been made with both junctions to determine the temperatures of the dry leaves, water was sprayed from an atomizer on the surface above one junction while the surface above the other junction was left dry. Readings were then made at intervals to determine the temperatures of the wet and dry portions of the leaf or, in the case of African violet and sedum, of the wet and dry leaves. In some experiments the water was blotted up and the leaf dried with filter paper or the water allowed to evaporate and the temperature again determined. In certain experiments the wet and dry sides were reversed to neutralize any differences in contact of the thermocouples with the leaves.

The results of several typical determinations are shown graphically in figure 1. In every instance, the presence of water on a leaf or portion of a leaf was accompanied by a reduction in temperature. The reduction varied from 4 to 12°C., the average reduction for all determinations being approximately 8.5°C. The amount of reduction in temperature seemed to vary with the leaf and air temperatures and with the humidity of the air. Since this study was concerned primarily with the effects of water drops on leaf temperatures, no extensive comparison of leaf and air temperatures was made. Air temperatures were determined by

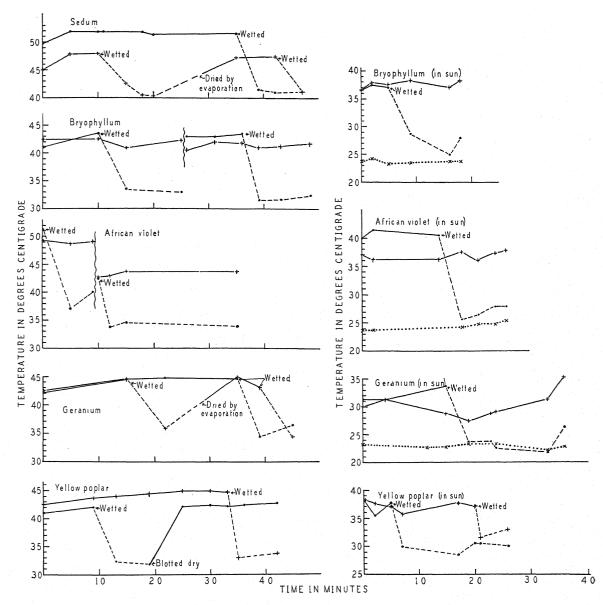

Fig. 1. Effect on leaf temperatures of wetting leaves. Each pair of lines represents simultaneous temperature determinations on a leaf or pair of leaves. Solid lines represent temperatures of dry leaves, broken lines represent temperatures of wet leaves. The dotted lines on the three graphs for species in the sun are air temperatures as determined by a shaded thermometer. The vertical lines on the graphs of African violet and bryophyllum separate determinations made on different leaves.

a shaded mercury thermometer in some experiments out-of-doors, however, and are shown by dotted lines on three graphs. It appears that the temperature of the wet leaves fell approximately to that of the air.

No difference was found between the behavior of hairy leaves, such as those of geranium and African violet, and smooth, highly cutinized leaves such as those of bryophyllum, camellia, and yellow poplar. The thick, succulent leaves of sedum behaved in the same manner as the thinner leaves of the other species. Water sprayed on the hairy

leaves tended to coalesce into films, but on the cutinized leaves it accumulated in drops. In some of the earlier experiments a single drop of water was placed on the leaf surface above the thermocouple junction, and the cooling effect was just as pronounced as when a larger area was wetted.

The results of these experiments are in accord with what would be expected on theoretical grounds. About 574 calories is required to evaporate one gram of water at 40°C. The removal of such a large quantity of heat would naturally materially decrease the temperature of the adjacent leaf tis-

sue. This would certainly more than compensate for any decrease in the cooling effect of transpiration.

Those who have suggested that drops of water on the leaves might act as lenses, concentrating the sun's rays and so burning the leaves, apparently have never calculated the focal length of such lenses. Observation of leaves after sprinkling indicated that drops from one to five millimeters in diameter are commonly present. Larger drops are usually irregular in outline, having resulted from

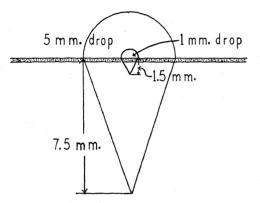

Fig. 2. Diagram showing focal distance of water drops acting as lenses on a leaf 0.5 mm. in thickness. Many leaves of course are much thinner.

the coalescence of several smaller drops. Very small drops evaporate so quickly in the bright sun that they could scarcely cause injury. Assuming that the average drop may be treated as a planoconvex lens, the focal length of a drop one millimeter in diameter is 1.5 millimeters or many times the thickness of the average leaf.2 Larger drops have correspondingly greater focal lengths. Large drops form somewhat flattened lenses which further increases their focal length. An attempt was made to measure the temperature by focussing on the junction of a thermocouple the visible rays from drops of water placed on a glass plate under a bright light. This was done for several drops of water, but no significant increase in temperature was observed. Considerable infra-red radiation is doubtless absorbed by the water and apparently very little reaches the focal point. Injury to leaves from a lens action of water drops on their surfaces is certainly rare and probably never occurs.

<sup>2</sup> The writer gratefully acknowledges the assistance of Prof. C. C. Hatley of the Physics Department in calculating the focal length of the water drops, and the aid of T. H. Wetmore and J. J. McDermott in making the determinations of leaf temperature.

It would seem probable theoretically that the presence of water on leaves might reduce rather than increase injury from overheating. This was tested by placing plants of several species so that their leaves were only a few inches from a 500 watt mazda lamp equipped with a reflector. Leaf temperatures of 50 to 60°C. were easily obtained, and leaves exposed to the light were killed in five to ten minutes. It was found, however, that leaves which were kept covered with a film of water applied from an atomizer remained uninjured, but that when the water was allowed to evaporate, the leaves were soon injured. When the water began to evaporate those areas which first became dry were the first to show injury, and no injury was ever observed under drops or films of water.

Watering plants during the middle of the day doubtless results in considerable wastage of water by excessive evaporation. Wetting the foliage also increases the possibility of fungus infections. It is further possible that injury may occasionally result from sprinkling leaves which bear bits of fertilizer or other foreign material. It is highly probable, however, that little or no direct injury ever results from the presence of water drops on leaves exposed to the sun.

## SUMMARY

The effect of drops of water on leaf temperatures was investigated by inserting thermocouples into leaves which were sprayed with water. thermocouples were usually inserted into a leaf, and the surface above one was kept dry while the surface above the other thermocouple was wetted. The leaves were exposed to the sun or to a 500 watt mazda lamp and the temperatures of the wet and dry portions determined. The temperature of the leaf areas covered with water drops was 4 to 12°C. lower than the temperature of the dry areas, the average reduction being 8.5°C. Wetted leaves placed a few inches from a mazda lamp remained uninjured, while dry leaves similarly exposed were killed by the heat. It was found that drops of water probably cannot cause injury by acting as lenses and concentrating the sun's rays on the leaf tissues because the focal length of such drops is usually much greater than the thickness of the leaves. It is concluded that injury to leaves from exposure to the sun while covered with water drops is much less common than popularly supposed, and possibly never occurs.

# PHOSPHATE RETENTION BY SAND IN RELATION TO SEEDLING CULTURE 1

# A. A. Dunlap

PHOSPHATES ARE known to be fixed by soil particles and by sand. When complete fertilizers are applied to soil, the phosphorus is one of the last elements to be leached out by rain. Similarly, the addition of nutrient solutions to sand cultures frequently results in retention of some phosphate by the sand. Although phosphates become fixed in a form that is insoluble in water, they still may be available to plants through the activity of the roots. Among the many soil studies on phosphate retention, the work of Ford (1933), Perkins and King (1936), and Beater (1937) may be mentioned.

In regard to the sand culture of seedlings, the importance of phosphate retention became evident in connection with certain experiments for the control of damping-off. It was noted that seedlings made as good growth in sand previously used with a complete nutrient solution, washed in water and then supplied only with KNO<sub>3</sub>, as in new sand with both KNO<sub>3</sub> and Ca(H<sub>2</sub>PO<sub>4</sub>)<sub>2</sub> supplied. Later it was found (Dunlap and Livingston, 1937) that considerable phosphate remained in the moist sand mass in a porous flower pot under continuous subirrigation, even after the K and NO<sub>3</sub> had been completely removed by evaporation and water movement.

As preliminary experiments, the growth of seedlings in new sand with only  $KNO_3$  added was compared with growth in the same kind of sand but with both  $KNO_3$  and  $Ca(H_2PO_4)_2$  supplied as plant nutrients. In this way, young plants of celery, lettuce, spinach, and tomato were found to respond markedly to the additional application of  $Ca(H_2PO_4)_2$ . On the other hand, barley, cabbage, flax, garden pea, kochia, and zinnia showed little difference in size of the seedlings when  $Ca(H_2PO_4)_2$  was included as a nutrient. In this connection the P-content of seeds is known to vary considerably between different species.

This paper reports the results of experiments on phosphate retention by sand as indicated by the early growth of plants from seed. A white, insoluble sand (Berkeley No. 18 mesh, Pennsylvania Glass Sand Corporation), practically neutral in reaction, was used as the culture medium for the plants. Over one hundred cultures of about 125 tomato seedlings each were grown in the greenhouse at the Connecticut Agricultural Experiment Station during the winter of 1937-1938. were two series of cultures. The first consisted of new sand entirely, with various nutrients [mostly KNO<sub>3</sub> with varying amounts of Ca(H<sub>2</sub>PO<sub>4</sub>)<sub>2</sub>] added. After the plants in the first series were harvested, the same sand was washed and used over again in the second series of cultures to which only KNO3 was added in most cases. Some of the cultures in each series contained sand that had been washed in 8 per cent HCl. In addition to the green-

<sup>1</sup> Received for publication October 25, 1938.

house cultures, laboratory studies were made to determine the relative rapidity and degree of phosphate retention when different types of sand were treated with solutions of  $Ca(H_2PO_4)_2$ . Except for certain modifications, the method for growing the experimental plants was the same as that described by Dunlap and Livingston (1937). The weights recorded below refer to the total, fresh, stem and leaf material produced by the entire culture 28 days after sowing.

Obviously the fresh-weight data obtained from the plants in the first series of cultures was in no way related to phosphate retention by the sand, since phosphates are available even after fixation. In the first series, cultures without added nutrients and receiving only tap water produced 5.5 gm, of fresh material. Those receiving a single-salt application of 1 gm. (about 0.01 gm.-mol.) of KNO<sub>3</sub> per culture produced an average fresh weight of 21.8 gm. Different applications of Ca(H<sub>2</sub>PO<sub>4</sub>)<sub>2</sub>, in addition to the above amount of KNO<sub>3</sub>, per culture at time of planting gave the following increases in fresh weight:

Amount of Ca(H <sub>2</sub> PO <sub>4</sub> ) <sub>2</sub>	Fresh weight of seedling						
0.000 gm.	21.8 gm.						
.004	22.2						
.02	34.2						
.1	46.3						
.5	56.5						
2.5	58.4						

It may be seen from the above figures that applications of 0.5 gm. (about 0.002 gm.-mol.) of  $Ca(H_2PO_4)_2$  in addition to 1 gm. of KNO<sub>3</sub> resulted, under these conditions, in practically the maximum amount of plant growth; and smaller quantities apparently were inadequate. When this phosphate application was increased five times [to 2.5 gm. of  $Ca(H_2PO_4)_2$  per culture], an increase in fresh weight of only about three per cent was obtained.

In the second series, only 6 gm. of fresh material were produced in the unfertilized sand. About 23.5 gm. fresh weight was recorded for those cultures that received only KNO3 for the second time in succession. The cultures that had received previously 0.5 gm. or less of Ca(H<sub>2</sub>PO<sub>4</sub>)<sub>2</sub> produced seedlings whose total fresh weights per culture were considerably less (mostly 25 to 30 gm. total fresh weight per culture) than those obtained in the corresponding culture of the first series. There was a marked increase, however, in the fresh weights of all cultures in the second series which previously had received 2.5 gm. of Ca(H<sub>2</sub>PO<sub>4</sub>)<sub>2</sub> as compared with the cultures which had received smaller amounts. The average fresh weight of 4 cultures that had received 2.5 gm. applications of Ca(H<sub>2</sub>PO<sub>4</sub>)<sub>2</sub> in the first series was 49.2 gm. This figure compares rather favorably with the 58.4 gm. obtained from previous plant growth in this same sand when the phosphate had been freshly added.

Acid treatment of the sand had no marked effect upon the growth of the tomato plants in the first series of cultures, as compared with untreated sand. In the second series, however, the plants growing in sand that was washed in acid before the first sowing of seeds were considerably smaller [about 30 gm. fresh weight, in each of those cultures that received 2.5 gm. of Ca(H<sub>2</sub>PO<sub>4</sub>)<sub>2</sub>] than those in cultures with sand that was washed only in water (about 49.2 gm. fresh weight) the first time the sand was used. This fresh weight of 30 gm. is noticeably greater, however, than the 23.5 gm. obtained in the cultures with sand that had received no phosphate in either series. Washing of the sand with acid just before replanting of the cultures resulted in uniformly poor growth in the second series (KNO3 only) regardless of the amount of Ca(H<sub>2</sub>PO<sub>4</sub>)<sub>2</sub> that had been added in the first

In place of the Ca(H<sub>2</sub>PO<sub>4</sub>)<sub>2</sub> used in the cultures mentioned above, some cultures of the first series were treated with KH2PO4 and others with K<sub>2</sub>HPO<sub>4</sub>, in addition to the KNO<sub>3</sub>. These two phosphates were substituted for the Ca(H<sub>2</sub>PO<sub>4</sub>)<sub>2</sub> in a few cases because of their different solubilities and pH values. In a limited number of tests there was little difference between the fresh weights obtained from these three sources of P, in either the first or second series of cultures. This would seem to indicate that phosphate retention had taken place in this type of sand regardless of differences in the initial pH of the nutrient solution. In the cultures to which KNO3 and Ca(H2PO4)2 were added, the initial hydrogen ion concentration of the nutrient solution was around 4.0 pH. However, the solution in the sand mass at the time the cultures were discontinued (28 days after planting) was found to have a pH value of 6.5 to 7.0.

The results of laboratory studies of the physical and chemical properties of certain different kinds of sand in relation to their phosphate-retaining capacities are given in table 1. The method of Truog (1930) with certain modifications<sup>2</sup> was used in ascertaining the amount of available P which remained in the sand after treatment with 0.1 per cent solution of  $\text{Ca}(\text{H}_2\text{PO}_4)_2$  for 5 days and then carefully washed.

Untreated samples of the above grades of sand gave very low tests for P (not more than 3 ppm. in any case), and all but a trace of this was removed by the acid treatment. When these acid-washed sands were treated with the 0.1 per cent  $Ca(H_2PO_4)_2$  solution, smaller amounts (as compared with sand washed only in water) of available P were found to be retained, as is shown by the figures in the last column of table 1. Results almost identical to those in table 1 were also obtained when

		same particle size as above sands)	1.6	1,

 ${\rm KH_2PO_4}$  was used in place of the  ${\rm Ca(H_2PO_4)_2}$ . When particles of the A type sand were separated according to size, the following data as to P retention was obtained: fine particles (0.3 mm. or less in diameter), 70 ppm.; medium particles (0.3 to 0.8 mm.), 38 ppm.; coarse particles (larger than 0.8 mm.), 41 ppm.

As to the rapidity of retention, untreated sand of the A type after standing in a 0.1 per cent solution of Ca(H<sub>2</sub>PO<sub>4</sub>)<sub>2</sub> for different periods of time was found to have retained P as follows: 1 hr., 16 ppm.; 2 hrs., 19 ppm.; 4 hrs., 30 ppm.; 1 day, 31 ppm.; 4 days, 36 ppm.; 7 days, 47 ppm. With a saturated Ca(H<sub>2</sub>PO<sub>4</sub>)<sub>2</sub> solution, 105 ppm. of P were retained in 2 hours and 280 ppm. in 7 days by this same type of sand.

Discussion.—Under the conditions of these experiments the phosphate requirements of tomato plants, weighing approximately 0.4 gm. each at an age of three weeks after emergence, were largely satisfied by phosphate retained in the sand in which the seeds were sown. The sand used in this case had a relatively low phosphate-retaining capacity as was shown by the laboratory tests. The retained phosphate had been added, as a soluble salt, in excess of plant needs to the sand at the time of planting a previous series of cultures. At least a part of this excess phosphate was not removed from the sand by several thorough washings in water; the phosphate was considered, therefore, to be retained in an insoluble state by the sand. The actual amount of phosphate potentially available to each plant would depend, obviously, upon the volume of sand within reach of the root system, and upon the amount of phosphate held in a given amount of sand. It has also been shown by the above laboratory tests that the most highly colored and finest grades of natural sand retained the most phosphate per unit weight. Screening out the finer particles or washing away the silt from the sand would tend to reduce the amount of phosphate retention. Washing of the

<sup>&</sup>lt;sup>2</sup> Tests supervised by Mr. H. G. M. Jacobson.

sand in acid also removes much of its phosphate-

retaining capacity.

From this work alone, conclusions as to the nature of the phosphate retention by sand would scarcely be justified. The fact that the results obtained with KH2PO4 were similar to those with Ca(H2PO4)2 would indicate actual fixation by the sand rather than merely mechanical retention of precipitated phosphate salts. The mere trace of P retention (1.6 ppm.) found with crushed glass of the same particle size as the sands used would also indicate that adsorption of the phosphate did not take place by this material. A chemical reaction may occur between the soluble phosphates and certain impurities of the sand. The marked retention of phosphate that was found in connection with the colored sands is in keeping with the belief that the Fe content of the sand influences the amount of fixation. Ford (1933) found that P fixed in soil as Fe and Al phosphates were at least in part easily hydrolizable and available to plants. He also showed that goethite and partially dehydrated bauxite formed phosphates that were crystalline on X-ray analysis. Such reactions between sand and a nutrient solution might alter the composition of the latter without materially changing its concentration, because of base exchange.

## SUMMARY

Young tomato plants fertilized with only KNO<sub>3</sub> in used sand, which in previous cultures had re-

ceived applications of  $\mathrm{Ca}(\mathrm{H_2PO_4})_2$  in excess of plant needs and then carefully washed, were practically equal in fresh weight to plants in new sand with both  $\mathrm{KNO_3}$  and  $\mathrm{Ca}(\mathrm{H_2PO_4})_2$  added. Treatment of the sand with acid lowered its phosphateretaining capacity as was shown by growth of the plants. The results of laboratory tests showing the amount of P retention as related to kind of sand, size of particle, acid treatment, concentration of the added  $\mathrm{Ca}(\mathrm{H_2PO_4})_2$  solution, and length of time of treatment with this solution are also given.

# NOTES ON THE SCUTELLARIAE OF EASTERN NORTH AMERICA. I

Carl Epling

GALERICULARIA.—While Scutellaria galericulata occurs widely throughout northern North America, its immediate associates fall into two species-groups -a western one, ranging from the Rocky Mountains to the Pacific, and an eastern one, lying largely east of the Mississippi River. The western species group, which is being dealt with in a separate paper, is the more diverse in habit. From the evidence which I have reviewed, it seems to me not improbable that at least two of those species, S. californica and S. antirrhinoides, have been derived through hybridization of some such prototypes as S. Bolanderi and S. angustifolia. Whether S. galericulata has played a part still earlier in initiating this complex (including also S. Austinae, siphocampyloides, and S. Brittonii) is difficult to determine.

In the eastern species-group, however, it seems to me both suggestive and helpful to assume that S. australis, S. nervosa, S. Leonardi, and S. parvula have all been derived by segregation from a complex which was initiated sometime during or after glaciation by S. galericulata and some such prototype as S. nervosa (or indeed, perhaps S. lateriflora), brought together perhaps by the events of

<sup>1</sup> Received for publication August 9, 1938.

the glacial periods. The relationships of the other species, here associated with *S. lateriflora*, are more obscure, but, as pointed out later, some relationship with that species seems probable.

I. S. galericulata L., Sp. Pl. 599. 1753.—The name S. epilobiifolia of A. Hamilton was taken up by Fernald (Rhodora 23: 85, 1921) to designate the American homolog of the Eurasian S. galericulata L. This action was based upon presumed differences in corolla size and color, differences in degree of pubescence, the fact that the leaves of the American plants are more cordate at the base than the Eurasian, and particularly upon the differences in size and pattern of the nutlets. After examination of a very large series of specimens from most of the larger American herbaria I have found that these conclusions may be sustained only in part.

It is impossible to determine finally either from herbarium specimens or published plates the differences in color. In so far as recent and well prepared specimens from both regions indicate, the differences are not significant, and seemingly the variation in pattern is about the same in both re-

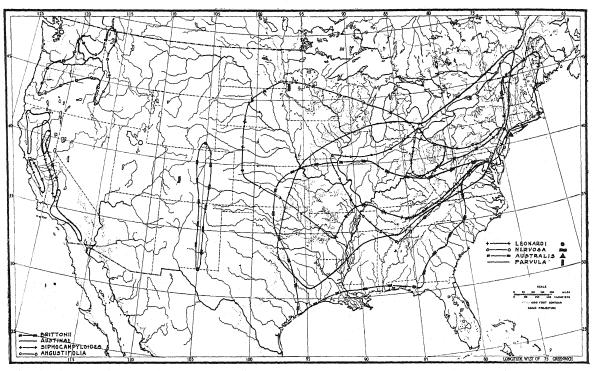

Fig. 1. A generalization from Map 2, showing the distributions in outline of the species of Galericularia. Although the relationships between the species within each group are about the same, as expressed in morphological characteristics, it will be observed that the ranges of the eastern species have become much less segregated than those of the mountainous western states. Apparent extra-limital occurrences are shown as follows: S. australis on Long Island; S. parcula in western Wisconsin; S. Brittonii in western Colorado and S. angustifolia in maritime Washington. A dubious form of the latter occurs in Utah.

gions. In degree and kind of pubescence the range of variation is about the same. Plants from Oregon and Washington may be wholly glabrous. They apparently may or may not occur with pubescent forms.

Such glabrous forms have been collected in Crook and Deschutes Counties, Oregon, and in Grant and Okanogan Counties in Washington. Apart from these wholly glabrous forms of the northwest, nearly glabrous forms are occasional in the eastern United States. Specimens from Siberia and Turkestan and occasional ones from western Europe show pubescence as dense as or denser than the specimens of the United States. The leaf-shape and habit have essentially the same range of variation on both continents. In corolla size there are certain modal differences. The range of variation in corolla length (tube plus galea, based upon boiled dissected specimens) of the comparatively few Eurasian plants which I have examined lies between 13 and 18 mm. The average is approximately 15 mm. The range of variation for the North American specimens lies between 14 and 21. The average is approximately 17.5 mm. There is also a modal difference in pattern of the nutlets, as suggested by Fernald. However, neither I, nor a colleague who kindly examined a mounted series have been able to effect a geographic segregation on this basis. In size the range of variation is essentially the same.

Since mature nutlets are generally lost in pressing, due to the habit of falling away which characterizes the upper lip of the calyx, they are difficult to study in the herbarium, and their range in variation is difficult to obtain. As far as one may judge in those instances where they have been preserved, they are frequently rather variable in pattern within a species. On the whole they apparently do not form a very trustworthy basis for specific segregation. It would appear that the deductions made by Penland (Rhodora 26: 61, 1924) were based upon an inadequate series of mature nutlets.

It is true, however, that there are racial differences between the plants of western Europe and those of Siberia and Turkestan. Furthermore, specimens indistinguishable from American and Siberian forms have been gathered in Sweden. In a few words, S. galericulata is fairly stable through most of its range in North America, save in Oregon and Washington. The extremes of the eastern United States may be duplicated in Eurasia, even in western Europe. However, the range of variation in western Europe is greater than in North America, and the extremes there apparently may not be duplicated here. In view of these facts, there appear to be, as yet, no satisfactory grounds for segregating S. epilobiifolia.

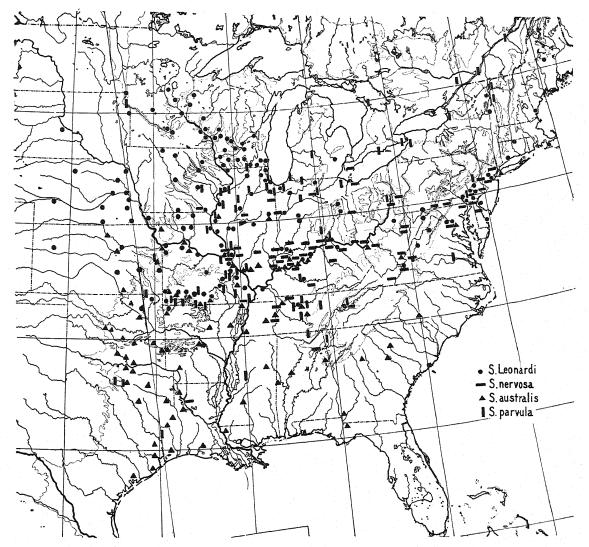

Fig. 2. A map showing the distribution in detail of Scutellaria nervosa, australis, parvula, and Leonardi.

2. S. nervosa Pursh, Fl. Amer. Sept. 412. 1814, based upon a specimen collected in Virginia; the probable type, collected at Winchester, Virginia, is in the herbarium of the Academy of Natural Sciences at Philadelphia.—S. teucrifolia J. E. Smith in Rees, Cycl. 32. no. 15. 1816, based upon the preceding.—S. gracilis Nutt., Gen. Pl. 2: 37. 1818, based upon a specimen collected by Nuttall in Pennsylvania on the banks of the Schuykill near Philadelphia; the type is in the British Museum.— S. ambigua Nutt., Gen. Pl. 2: 37. 1818, based upon a specimen collected by Nuttall in Ohio in dry and open forests; the type or a portion of it is in the herbarium of the Royal Botanic Gardens at Kew; a fragment of apparently the same plant is in the herbarium of the Philadelphia Academy; none are in the British Museum.—S. parviflora Hamilt., Monogr. 37. 1832, based upon a specimen collected by Rafinesque in Ohio; the type is in the DC. herbarium.—S. parvula var. ambigua Fernald in Rhodora 3: 201. 1901, as to name only, based upon S. ambigua Nuttall.

A perennial herb spreading by slender rhizomes, its stems now simple, now branching somewhat towards the base, sprinkled in the lowermost parts with spreading capitate-glandular hairs, in the upper parts with upwardly curving appressed hairs chiefly along the angles, sometimes wholly glabrous; blades of the lowermost leaves cordate-ovate, 1-1.5 cm. in diameter, sprinkled on both surfaces with spreading capitate glands, borne on petioles .5-2.5 cm. long, those of the median leaves generally ovate, sessile, 20-45 mm. long (averaging about 35 mm.), 12-36 mm. broad (averaging about 20 mm.), their margins unevenly crenate-dentate, those of the uppermost entire, the upper surfaces appressed hirsute, especially towards the margins, the lower hirtellous along the veins with curving hairs; flowers disposed above the middle on pedicels which are ascendent-hirtellous; lower calyx lip 2.5-3 mm.

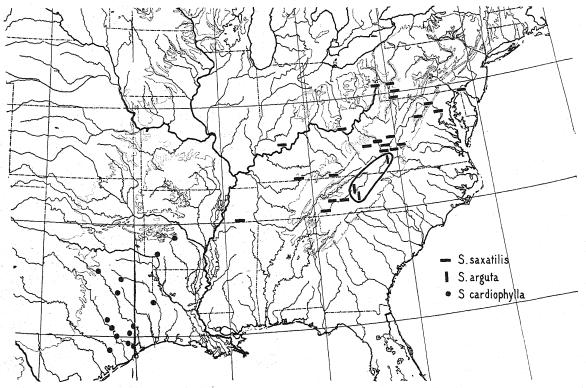

Fig. 3. A map showing the distribution of Scutellaria arguta, saxatilis, and cardiophylla.

long at flowering, 5-6 mm. long at maturity, hirtellous, the squama about 4 mm. tall, concave, galea and tube 8-10 mm. long, the lower lip hirtellous in two lines, the lower filaments seated below the middle of the tube; nutlets brown or nearly black, covered with peg-like processes, usually banded.

The principal variation of this species lies in the shape of the leaves, whether tending to rotund or deltoid. The former condition is more prevalent. Occasional specimens occur which suggest an intermixture with S. Leonardi, such as those of Short from Blue Lick, Kentucky. Perhaps such specimens, which seem largely confined to Kentucky, Indiana and Illinois are resultant from incomplete segregation of an earlier complex from which S. Leonardi has also been derived. Such specimens have little to distinguish them from S. Leonardi save in the larger parts throughout. Pursh's specimen of S. nervosa is very similar to the plants collected near Washington, D. C., such as those gathered by Shelden or Kearney. Nuttall's type of S. gracilis is fairly average. His type of S. ambigua however, which is closely matched by Lloyd's collections from Cincinnati and by those of Frank (anno 1835) from the same region, is clearly conspecific with S. nervosa and not with the plant here designated S. Leonardi. Comparison of the pubescence of this specimen with a large series of specimens including the smallest branch of the Pursh sheet and such specimens as Lloyd's, as has been done by the author, is convincing of their conspecificity. The species occurs consistently in woods in springy places or along streams.

3. S. Leonardi nom. nov. S. ambigua Leonard and other authors, not Nuttall.—S. parvula var. ambigua Fern. in Rhodora 3: 201. 1901, excluding Nuttall's specimen; Nuttall's specimens at Philadelphia labelled "Scutellaria parvula or var.," consist of S. australis and S. Leonardi. Pursh's specimens of "S. parvula" are S. Leonardi.

A small perennial herb creeping by moniliform rhizomes, its stems usually branched at the base, erect, generally 10-20, rarely 30 cm. tall, sprinkled in the lowermost parts with small spreading capitate glands, elsewhere minutely appressed-hispidulous along the angles, appearing glabrous, rarely completely so; lowermost leaf-blades rotund-ovate, usually 4-8 mm. in diameter, sparingly hirsute on the upper surfaces, borne on petioles 3-8 or rarely 11 mm. long, the median 4-6 mm. broad (averaging about 5.5 mm.), 11-16 mm. long (averaging about 13 mm.), sessile, narrowly deltoid-ovate, quite entire, rarely irregularly dentate toward the base, glabrate on both surfaces, being minutely appressedhispidulous only toward the margins and somewhat revolute; flowers disposed above the middle, the pedicels ascendent-hirtellous; lower lip of the calyx 2-3.5 mm. long at flowering, 4-5 mm. long at maturity, the squama 2-3 mm. tall, concave; galea and tube 6.5-9 mm. long, the lower lip hirtellous in two lines, the lowermost filaments seated near the middle of the tube; nutlets brown, covered with peglike processes, usually banded.

Throughout its range S. Leonardi is rather constant and may readily be recognized by the nature of its pubescence as well as by the habit and shape of its leaves. As pointed out above, it appears as a diminutive of the stricter forms of S. nervosa and frequently suggests a diminutive S. galericulata. That the two occur together in some regions seems certain. It is a pleasure to associate with this species the name of Mr. Emery C. Leonard who, in his careful and useful revision, recognized the specific distinctions clearly but, lacking access to the type at Kew, was misled as to the name.

4. **S. australis** sp. nov.—S. parvula var. australis Fassett in Rhodora 39. 378. 1937, based upon a specimen collected by Fassett (no. 18063) on sandstone ledges near White River, Goshen, Arkansas; the type is in the herbarium of the University of Wisconsin.

A small perennial herb creeping by moniliform rhizomes, its stems erect, usually branching at the base, generally 10-30 cm. tall, sparingly clothed along the angles usually with appressed-ascendent hairs and with longer spreading capitate glands, rarely eglandular; blades of the median leaves sessile, ovate and entire, rarely deltoid-ovate, and sparingly dentate, prevailingly 7-10 mm. broad, 10-15 mm. long, those of the lowermost subrotund,

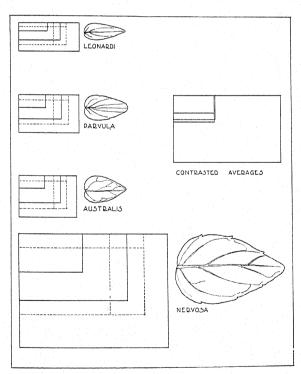

Fig. 4. A chart showing the minimum, average and maximum sizes in proportion of the median leaves (lowermost floral leaves) of Scutellaria nervosa, australis, parvula, and Leonardi. The ordinary deviations from the average are shown in broken lines. The usual shapes are shown in the outline drawings. The drawings were made from the data in table 1.

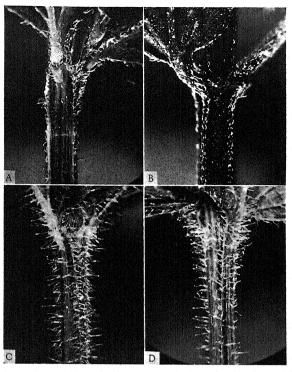

Fig. 5. Photographs illustrating the pubescence types of (a) Scutellaria nervosa, ×12; (b) S. Leonardi, ×13; (c) S. parvula, ×13; (d) S. australis, ×12.

usually 7-12 mm. in diameter and borne on petioles 5-15 mm. long, all sprinkled on both surfaces with rather long capitate glandular hairs, rarely glabrate; the veins prominent and tending to branch and anastomose along the margins; flowers disposed above the middle of the plant on pedicels which are ascendent-pubescent, but hardly appressed; lower lip of the calyx 2.5-3 mm. long at flowering, 4-5 mm. long at maturity, the squama 3.5-4.5 mm. tall, sprinkled with capitate glands, concave; galea and tube 7-10 mm. long, the lower lip hirtellous in two lines, the lower filaments seated near the middle of the tube; nutlets brown, covered with peg-like processes, usually banded.

The data concerning pubescence furnished by Professor Fassett is wholly in accord with my own observations previously made. By reason of these absolute differences, as well as the modal differences in leaf habit and the facts of distribution, it has seemed desirable to accord specific recognition to this plant. Just as S. Leonardi suggests a diminutive of the strict forms of S. nervosa, S. australis suggests in many ways a diminutive of the more average forms of that species. It will be observed that the average proportions of the leaves are almost identical. Their texture is similar.

Occasional specimens occur which appear to be intermediate with S. Leonardi, having the habit of that species but the pubescence of S. australis. Such specimens have been found at Grantville and

at Windsor Springs, Missouri. Still other specimens occur, which, while otherwise similar to S. australis, are wanting in the spreading glands. The ascendent, appressed hairs are coarser than those of S. Leonardi. Such specimens have been collected at Dillerville, Pennsylvania; Alexandria, Louisiana; Terrell, Texas; and Houston, Texas. A specimen collected by Gleason near Urbana, Illinois, was apparently cleistogamous. It, with other flowering specimens collected at Champaign by the same collector, suggest S. Leonardi in habit. A specimen collected at Fulton, Arkansas, is nearly glabrous.

point where they leave the calyx. They are accordingly erect. Those of S. cardiophylla are similar but less abruptly curved.

6. S. Churchilliana Fern. in Rhodora 4: 137. 1902, based upon a specimen collected by Fernald at Masardis in the Aroostook Valley, Maine; the

type is in the Gray Herbarium.

As suggested by Fernald and by Penland, this is not improbably of hybrid origin between S. galericulata and S. lateriflora, being about intermediate with the presumed parents. It is fairly stable. It may readily be distinguished from S. galericulata by the size of the corolla and the

5. S. parvula Michx., Fl. Bor. Am. 2: 11. 1803, based upon specimens collected in Illinois and in Canada near Montreal; the type, bearing both specimens, is in the Museum of Natural History at Paris.—S. parvula var. mollis Gray, Syn. Fl. 2: 380. 1878, based upon specimens collected by Patterson at Oquawka, Illinois; the type is in the Gray Herbarium.—S. campestris Britton, Mem. Torrey Bot. Club 5: 283. 1894, based upon the preceding.

A small herb, spreading by moniliform rhizomes, its stems usually erect, branching at the base, 10-30 cm. tall, covered evenly and densely with subretrorse or spreading hairs and with larger capitate glandular ones, frequently bearing only the glandular hairs in the lower parts; median leaf-blades sessile, deltoid-ovate, rarely ovate, usually irregularly subdentate, for the most part 8-19 mm. long, 4-12 mm. broad, the lowermost subrotund, usually 7-12 mm. in diameter, borne on petioles 5-15 mm. long, the upper surfaces of all hirsute with capitate glands, the lower clothed like the stems, also more or less sprinkled with sessile golden glands; flowers disposed above the middle of the plant, borne on retrorse-hirtellous pedicels; lower calvx lip 2.5-3 mm. long at anthesis, 4-5 mm. long at maturity, the squama 3-3.5 mm. tall, concave, clothed like the stems; galea and tube 7-10 mm. long, the lower lip hirtellous in two lines, the lower filaments seated near the middle of the tube; nutlets brown or black, covered with peglike processes, banded.

LATERIFLORAE.—The following section is by no means as homogeneous as the species group termed Galericularia. However, the impression that the four species here associated with it are derivatives of S. lateriflora perhaps through hybridization cannot be avoided, despite the differences in conformation of the corolla. It will be noted that the corolla tubes of S. saxatilis and of S. arguta are enlarged somewhat and abruptly geniculate at the

ascendent pubescence; from S. lateriflora by the size of the flower. In Maine it occurs in Aroostook, Penobscot, and Androscoggin Counties. It has also been collected in New Brunswick (Carleton County) and in Quebec (Rimouski County).

7. S. lateriflora L. Sp. Pl. 598. 1753.—The range of S. lateriflora lies between 30° and 50° latitude, save in western Canada, where it ranges farther north. There are no records for Mexico. It is infrequent, however, south of 35°. It is most abundant in the drainages of the Ohio and St. Lawrence Rivers. A form occurs in which small capitate glands are sprinkled through the inflorescence and on the calvees in addition to the appressed hairs. This glandular form has been found as far south as Arkansas, Mississippi, and Georgia and as far west as Oklahoma and Minnesota. It would appear to center in Pennsylvania, being more frequently collected there than the eglandular form. It is equally abundant in New York, the New England States, and the maritime provinces of Canada. It is less frequent as one proceeds southward and westward. It is infrequent west of the Mississippi River and apparently does not occur west of the Plains States, save for one record in Arizona.

8. S. saxatilis Riddell, Cat. Ohio Pl. Suppl. 14. 1836, based upon specimens collected by Riddell on a dry hill 3 mi. southwest from Chillicothe, Ohio, and on arid cliffs in Kentucky opposite the mouth of the Scioto River; authentic specimens are in the Gray Herbarium, the National Herbarium and in the Torrey Herbarium.—S. Chamaedrys Shuttlw. ex Benth. in DC. Prodr. 12: 422. 1848 (a name published in synonomy).

A perennial herb spreading by threadlike stolons, its stems commonly 20-40 cm. long, weak and slender, usually reclining, spreading glandular in the lowermost parts, quite glabrous or sparingly hirtellous with appressed ascendent hairs in the

middle parts, the inflorescence, at least the pedicels, glandular with spreading hairs and often with ascending appressed ones, rarely quite glabrous; lowermost leaf-blades broadly ovate-cordate, tending to reniform, borne on petioles about as long as the blade, the median usually deltoid or deltoidovate; commonly 2-5 cm. long, crenate or serrate, borne on slender subequal petioles, passing rather abruptly into the diminished elliptical or ellipticallanceolate entire floral leaves, all usually glabrate, being ciliate on the margins, rarely quite glabrous. rarely thinly hirsute on both surfaces; flowers disposed in slender bracteate racemes 5-15 cm. long, some frequently on the axils of the upper leaves, borne on pedicels which are hirtellous with usually ascendent hairs and commonly with spreading glandular hairs as well; flowering calvees hirtellous and glandular, similar to the pedicels, the lower lip 2-2.5 mm. long at anthesis, 4.5-5 mm. long at maturity, the squama about 3.5 mm. tall, concave; galea and tube 14-19 mm. long, the lip glabrous, the tube sparingly pilose within along the under side; lower stamens seated 9-10 mm. above the base of the tube; nutlets a warm brown, covered with papillate processes.

A form with median leaves ovate, rather than deltoid, has been collected at Rockford and at Wilmington, Delaware. A form nearly glabrous, with diminished leaves and longer petioles has been collected near Nuttallburg, West Virginia. A similar form, quite eglandular, has been collected at Alderson, West Virginia. These are similar to Rügel's specimen from Warmsprings, Tennessee (S. Chamaedrys Shuttl.). Following is the known distribution of this species by counties: Pennsylvania: Fayette, Westmoreland, Beaver; Delaware: New Castle; Maryland: Montgomery; Virginia: Rockbridge, Pulaski, Arlington, Craig, Warren, Giles, Fairfax; West Virginia: Greenbriar, Fayette, Pocahontas, Boone, Jefferson; Ohio: Jefferson; Kentucky: Bell, Greenup, Monroe; Tennessee: Fayette, Polk, Blount, Cocke; South Carolina: "West Point."

9. S. arguta Buckley in Amer. Jour. Sci. 45: 175. 1843, based upon specimens collected by him on Black Mountain (Mt. Mitchell) in North Carolina.—S. saxatilis var. arguta Gray, Syn. Fl. N. Am. 2: 379. 1878, based upon the same.—S. saxatilis var. pilosior Benth. in DC. Prodr. 12: 423. 1848, based upon a specimen collected on Black Mountain by Rügel; the type is in the herbarium of the Royal Botanic Gardens at Kew.

A perennial herb spreading by threadlike stolons, its stems commonly 20-40 cm. tall, commonly branching near the base and ascendent, less often reclining, glandular throughout with rather dense spreading capitate glands and usually pubescent in the upper parts, even cinereous, with small retrorse eglandular hairs; lowermost leaf-blades broadly ovate-cordate, tending to reniform, borne on petioles about as long as the blade, the median ovate, somewhat cordate at the base, commonly 2-5

cm. long, sharply and strikingly serrate, borne on slender petioles as long as or even twice as long as the blade, passing rather abruptly into the diminished ovate and usually dentate floral leaves, all usually thinly hirsute on both surfaces; flowers disposed in slender bracteate racemes 5-15 cm. long, some frequently in the axils of the upper leaves, borne on pedicels which are clothed with retrorse glandular hairs; flowering calvees hirtellous with spreading hairs, both small eglandular ones and longer capitate glands, the lower lip usually 3-3.5 mm. long at anthesis, 5-5.5 mm. long at maturity, the squama about 3.5 mm. tall, concave, galea and tube 15-19 mm. long, the lip glabrous, the tube glabrous or sparingly pilose at the base above the angle; lower stamens seated 9-10 mm. above the base of the tube; nutlets a warm brown, covered with peg-like processes.

In so far as one may judge from the meager representations to be found in our herbaria, this species is relatively stable. It is doubtless highly localized. The flowers appear to be identical with those of S. saxatilis, save in the pubescence within the tube. However, it is difficult to perceive from dried specimens, even when boiled, what may be significant differences in conformation. As with S. saxatilis, the throat is seemingly open. The general habit is more strict than in that species. The nutlets are similar but not identical. I have seen only one example of a mature nutlet, together with three immature examples, and not many more than this of S. saxatilis. Judged on this slender basis, the patterns which the nutlets present appear to be significantly different, the processes of S. saxatilis being distinctly papillate and crowded, those of S. arguta more peglike and not crowded. The differences in pubescence and leaf-habit appear to be constant. The petioles appear to be constantly longer in proportion to the blade.

The known occurrence of S. arguta is as follows: Virginia: Montgomery, Blacksburg, Giles, Glenlyn; Tennessee: Unicoi, Unaka Springs; North Carolina: Yancey, Mt. Mitchell, Buncombe, Mon-

treat.

10. S. cardiophylla Engelm. and Gray in Bot. Jour. Nat. Hist. 5: 227. 1845, based upon specimens collected by Lindheimer in open woods near Houston, Texas, and by Drummond (no. 209); it is difficult to assign to a single specimen the rôle of "type." The Drummond plants in the Gray and Torrey herbaria are fragmentary and ill-pressed. Lindheimer gathered several specimens at different times, but Engelmann did not annotate those in his own herbarium. Perhaps the best choice of a standard would be Lindheimer no. 144 in the Gray Herbarium. It is very similar to a specimen in Engelmann's herbarium which bears the published data as to place of collection of the type.

An annual, 40-60 cm. tall, rather strict and stiffish, branching freely above the middle, the branches ascendent and strict, clothed with recurved, appressed hairs, particularly along the

angles, sometimes with spreading glandular hairs in the lowermost parts as well; basal leaves soon deciduous, the median deltoid, lightly cordate, commonly 2-5 cm. long, crenate-dentate, the lower borne on petioles as long as the blades, the uppermost subsessile and subentire, gradually diminished, the upper surfaces of all glabrous, the lower hispidulous with spreading hairs, their margins usually ciliate with longer hairs; flowers produced in the upper parts of the plant in the axils of gradually diminished leaves, the pedicels clothed like the stems; flowering calvees retrorse-pubescent and ciliate on the margins, the lower lip 4-4.5 mm. long at anthesis, 5-6 mm. long at maturity, the squama about 3.5 mm. tall, concave; galea and tube 13-22 mm. (generally about 18 mm.) long, the tube pilose

within, the lip glabrous; lower filaments seated 7-13 mm. (usually about 11 mm.) above the base of the tube; nutlets black, shallowly papillate.

Save for the variation in flower size which is indicated above, this species is fairly stable. It is possible that the plants of Arkansas represent a small flowered race with corollas 13-17 mm. long. The known range of this species by counties is as follows: Arkansas: Garland, Hempstead; Texas: Anderson, Galveston, Brazos, Montgomery, Smith, Cherokee, Harris, Matagorda, Colorado, Waller, Dallas, Walker, Robertson, San Augustine.

# THE DUAL EFFECT OF AUXIN ON ROOT FORMATION 1

F. W. Went

Soon after the discovery that the root forming hormone as determined in the pea rooting test (Went, 1934) is identical with auxin (Thimann and Went, 1934, Thimann and Koepfli, 1935), it became clear that auxin is only one of the many specific internal factors involved in root formation. Several such factors have been listed and described elsewhere (Went and Thimann, 1937, Went, Bonner and Warner, 1938). In addition to the chemically well defined factors such as auxin, biotin, carotin, folliculin, vitamin B<sub>1</sub>, and amino acids, a number of experiments pointed towards the existence of a specific root forming hormone, rhizocaline (Went, 1936, 1938, Cooper, 1936, 1938). The concept of rhizocaline as used in this paper is essentially the same as it was when originated by Bouillenne and Went (1933) for "a special substance causing the initiation of roots," exclusive of chemically known substances such as auxin. The experiments suggested that the rhizocaline is redistributed inside the plant under the influence of auxin. The experiments of Cooper (1938) lead to the assumption that the root forming action of auxin must be two-fold. In the first place, the auxin causes an accumulation of rhizocaline near the point of application, and secondly, auxin activates or reacts with the rhizocaline. The present paper aims to present more and independent evidence for this dual effect of auxin on root formation.

EFFECTIVENESS OF DIFFERENT SUBSTANCES IN THE INDUCTION OF ROOT FORMATION.—In tables 1 and 2 the result of two experiments are recorded. For details concerning the technique of the experiments reference may be made to Went (1934). Stem cuttings of etiolated peas were treated either at their split tips or at their bases with a number of different substances, all known to be active in pro-

<sup>1</sup> Received for publication October 1, 1938.

This work was carried out with the help of the Works Progress Administration, Work Project No. 6989, Official Project 165-03-6999.

ducing growth and all previously reported by Zimmerman and Wilcoxon (1935) to have root forming activity. That these substances should be retested on peas was desirable for two reasons: (1) quantitative data which might be directly compared with previous results were required, and (2) determinations carried out with auxin-free material were necessary. The experiments of Michener (1935) show that the latter condition is important. For ethylene seems effective in root formation only when auxin is present in the cutting. Therefore, in green herbaceous cuttings containing auxin, Crocker, Zimmerman, and Hitchcock (1933, 1935) found a very distinct rooting response to ethylene, while Michener found that in peas or Salix cuttings, poor in auxin, ethylene did not affect root formation.

From table 1 it appears that, of the various substances applied at the tip, indole acetic acid is by far the most active in causing root formation, after which, in order of decreasing activity, follow indole butyric and anthracene acetic acid. Indole propionic acid does not appreciably affect root formation. Since these substances become effective only at the base, their activity might be expected to depend on their transport rate inside the pea stem (Thimann, 1935). Recently the transport velocities for these substances in the Avena coleoptile were measured (Went and White, 1939), and the following values were obtained: indole acetic acid, 9.0 mm./hour; indole butyric acid, 6.5 mm./hour; anthracene acetic acid, 5.4 mm./hour; indole propionic acid, 4 mm./hour. Since the activities of these substances when applied at the base is approximately the same (only anthracene acetic acid is somewhat less active, according to table 2), it appears that the transport velocity is one of the main properties affecting root forming activity of a substance applied from the apex of a cutting. If the substances are applied at the base, differences in transport velocity do not seem to play an impor-

tant part, and the different indole, anthracene, and naphthalene compounds all have a comparable ac-In another experiment, indole propionic acid was found to be much less active, just as in table 1, and in agreement with Thimann and Koepfli (1935). In the experiment of table 2, indole butyric appears to be slightly (although not mathematically significantly) more active than indole acetic acid, but this was not confirmed in other experiments. The decrease in activity at the highest concentrations of the indole compounds is due to toxicity, which was very marked with the indole valeric acid. Since in homologs permeability increases with increasing length of the C-chain (see e.g. Collander and Bärlund, 1933), the increased toxicity must be due to greater permeation.

This approximately equal activity of the indole, naphthalene, and anthracene compounds, when differences due to unequal transport are excluded, compares very well with the equal activity of these compounds in growth (Koepfli, Thimann and Went, 1938; D. Bonner, 1938) and seems to substantiate Thimann's rule (1935) that a substance active in the growth reaction will cause root formation as well. A notable exception, however, is phenyl

acetic acid. Since this exception constitutes a main point in the argument to follow, and also since it is of special importance in connection with the hypothesis that all substances causing growth, root formation, bud inhibition, etc., are doing so by taking part in one master reaction (Thimann, 1935), the effect of phenyl acetic acid on root formation has been determined in many different experiments, involving a total of many hundreds of pea stems. In no single experiment, however, has a significant increase in the number of roots formed under the influence of any concentration of phenyl acetic acid by itself ever been detected.

Analysis of the effect of indole acetic acid on root formation.—In pea stems the applied auxin tends to make the rhizocaline collect at the cut surfaces (Went, 1938). This should decrease its concentration in the middle portion of the stem. In lemon cuttings Cooper (1936, 1938) was able to demonstrate that when the auxin treatment was just right, the stem above the treated base could not root any more. This could be explained on the basis of a depletion of rhizocaline. Hellinga (1937) claims that Gouwentak's and his results (1935) do not support this view. However, they did not treat

Table 2. Root formation (in roots per 10 plants) on etiolated pea stem cuttings. Treated for 16½ hours at base with various concentrations of various compounds. Each figure is the mean of 10 plants, except where noted.

their cuttings with auxin previous to making the new cut surface. Also, the experiments of Pearse (1938) do not furnish evidence against the depletion hypothesis, since most of the developing roots grew from pre-existing root primordia.

In etiolated pea stems such a depletion was still more difficult to demonstrate. Only in the experiments which gave the best root formation after an initial indole acetic acid treatment was a decreased rooting response of the middle portion of the stem

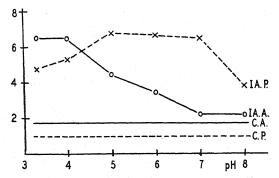

Fig. 1. Number of roots (ordinate) formed per pea cutting 10 days after treatment. Abscissa: pH of solution during 15 hour pre-treatment (IA.P.) or 15 hour after-treatment (IA.A.). The cuttings from IA.P. and C.P. were both after-treated with indole acetic acid 200 mg/l at pH 6; IA.P. were pre-treated with indole acetic acid 200 mg/l at various pH, C.P. with water at pH 6. IA.A. cuttings were after-treated with indole acetic acid 200 mg/l at different pH, C.A. with water at pH 6; the pre-treatment of both IA.A. and C.A. was with indole acetic acid 200 mg/l at pH 6.

noticeable. But whenever the root formation was less than 10 roots per plant (so that, according to Went (1938), enough rhizocaline was left to cause 40-10=30 roots to develop), no decrease in rooting response of the rest of the stem could be detected.

Table 3 shows an experiment in which pre-treatment for 15 hours with a high indole acetic acid concentration, followed by cutting off the basal 1 or 2 cm., decreased the root formation when the same stems were after-treated with indole acetic acid. Table 3 indicates also why in other experiments this effect was not observed. The pre-treatment with indole acetic acid was able by itself to induce root

formation in the basal zones when 1 or 2 cm. were cut off (after treatment with water). In many cases this rooting in the peas after-treated with water was so extensive that all other effects were overshadowed by it.

Whereas these experiments carried out under conditions of low rooting response of the peas cannot be used to demonstrate a depletion of rhizocaline in the upper parts of the cuttings, under just those conditions another phenomenon was discovered. It was observed in many experiments that the sum of the number of roots formed after either pre-treatment for 15 hours with auxin or 15 hours aftertreatment with auxin did not equal the number of roots formed after both pre- and after-treatment (30 hours) with auxin (see table 4). This means that the processes taking place during pre- and after-treatment are not identical. This same conclusion was reached for the pea test (Went, 1939), and there it was shown that the substances causing curvature not only took part in two reactions separated in time, but that also those reactions had a different pH sensitivity, the preparatory reaction being pH independent, the following growth reaction being the pH sensitive reaction. The pH dependence of the processes taking place during pre-treatment and after-treatment was therefore investigated for root formation also. Since there is no visible separation between these processes, a more or less arbitrary time interval was chosen for each of them. An experiment with a particularly clear result is presented in figure 1. The buffer solution somewhat decreased the rooting. It will be seen that when the pH of the indole acetic acid solution was varied during the pre-treatment (I.A.P.), the rooting response was somewhat less only at pH 3.3, 4, and 8, but around the pH of the cells (6) no effect of acidity was found. But for the after-treatment a pH dependence similar to that described by Bonner (1934) for the growth reaction existed. This can be explained along the same lines: during after-treatment only the undissociated molecules of indole acetic acid are active, and therefore the activity at pH 7 and 8 is very low.

THE EFFECT OF PHENYL ACETIC ACID AND CERTAIN NON-AUXINS ON ROOT FORMATION.—From the experiments of tables 1 and 2 it is evident that phenyl acetic acid by itself has no effect on root formation in pea cuttings. Considering (1) that in

green herbaceous cuttings it causes root formation (Zimmerman and Wilcoxon, 1935), (2) that a pretreatment with indole acetic acid increases the effectiveness of an after-treatment with the same substance, and (3) that in the pea test certain substances (hemi-auxins (Went, 1939)), not causing growth themselves, greatly increase the effectiveness of auxins, the effect of phenyl acetic acid during pre- and after-treatment was tested. Seven experiments, each involving hundreds of pea cuttings, gave qualitatively the same results, and two are reproduced in table 4 (see also table 5). It is evident from these results that phenyl acetic acid can take the place of indole acetic acid in the pretreatment, although quantitatively its effect is less. But in no case had it any effect as an after-treatment. This means that phenyl acetic acid can take part in only the first of the two successive reactions in which auxin takes part and which lead towards root formation. In this connection it is interesting to note that in two experiments there were indications that cutting off the base of a pea stem after pre-treatment with phenyl acetic acid, as compared to pre-treatment with water, decreased the subsequent response to indole acetic acid.

More striking still than the partial activity of phenyl acetic acid in root formation is the effect of certain substances which have no trace of growth promoting activity. Traub (1938) reported on the effectiveness of many substances, including sodium naphthol sulfonate, potassium anthraquinone sulfonate, anthranilic acid, and calcium furoate, in causing root formation on cuttings of Passiflora. Since the plants with which he worked were green and presumably full of auxin, experiments were performed in which these substances, kindly supplied by Dr. H. P. Traub, were tried on etiolated peas. Special tests showed that they were completely inactive in causing the growth reaction or the preparatory reaction in the pea test (see Went, 1939). But without doubt they all were active as pre-treatment for root formation if the peas were after-treated with indole acetic acid. By themselves, however, they did not give any root formation at all (see table 6). The same effect was found for  $\gamma$  phenyl butyric acid (table 5). Thus it has been demonstrated that there exist a group of substances which by themselves are not able to cause the formation of roots, but which greatly facilitate root formation in the presence of auxin or indole acetic acid. It also was found that this effect has to precede the actual root formation by auxin to be noticeable.

Discussion.—As mentioned in the introduction, earlier experiments by Went and Cooper demonstrated that the effect of auxin on root formation was not simple. Beyond participating in the differentiation of root primordia, at least one more reaction was recognized—namely, the redistribution or diversion of specific root forming factors (rhizocaline). In Went's experiments (1936, 1938) the accumulation of the rhizocaline at the place of auxin application or accumulation was demonstrated. Cooper's experiments (1936, 1938) showed how the remainder of the stem was emptied of rhizocaline after the auxin treatment.

In the present paper another method was used to demonstrate the dual effect of auxin on root formation. It was found by differentiating the effect of auxin in a first and second period of application that these effects were not additive, but that under the proper conditions neither pre- nor after-treatment had any visible effect by themselves. A combination of pre- and after-treatment was always more effective than the additive effects of either one alone. This difference in action could be made much clearer by using various substances during pre- and after-treatment. In the case of phenyl acetic acid it was clearly shown that, although this substance was unable to cause any root formation in the pea cuttings which were used, it was almost as

Table 6. Number of roots formed in 40 pea stems each. For the pre-treatment four concentrations (50, 100, 200 and 400 mg/l) of the three substances listed were used.

After-treatment for 24 hrs.	Indole acetic acid 100 mg/l	Water

active during pre-treatment as indole acetic acid. No visible effect of this pre-treatment became evident unless the peas were after-treated with indole acetic acid or some other substance with true root-forming activity.

Since phenyl acetic acid has true growth activity, although lower than that of indole acetic acid (Koepfli, Thimann, and Went, 1938), it might be argued that its root forming activity was too low to be detectable in the tests. Such an argument is difficult to disprove, but with the highest concentration of phenyl acetic acid not even a trace of root forming activity was discovered. That it was effective as pre-treatment in much lower concentration is proven by tables 4 and 5. Other experiments, however, make it practically certain that in pre-treatment and after-treatment completely different reactions are involved. Many substances, like y phenyl butyric acid, sodium naphthol sulfonate, etc., which possess no trace of true growth promoting activity, are effective during pre-treatment (tables 5 and 6) but are absolutely ineffective during after-treat-

In all cases in which these substances, which are active during pre-treatment only, were found to cause root formation (Zimmerman and Wilcoxon, 1935; Traub, 1938), green cuttings containing auxin were used. From the experiments described above, the conclusion is evident that the auxin in those cuttings was sufficient to cause the after-treatment effect. Therefore, substances effective only in producing the first step towards root formation, but not actually taking part in the specific root

forming reaction, may seem active when the effectiveness of the auxin present in the cuttings has been increased. This is exactly what ethylene does (Michener, 1935). It therefore becomes evident that great care must be taken in drawing conclusions concerning root formation from experiments with green cuttings that contain auxin.

Evidence, although meager, has been presented to indicate that the pre-treatment reaction is identical with the redistribution effect on rhizocaline. The second reaction, which takes place during after-treatment, most likely consists of the reaction of auxin with rhizocaline, which results in the redifferentiation of the stem tissues into root primordia.

The very interesting investigations of Scott (1938) on the anatomy of differentiation of the tissues of the pea stem after application of indole acetic acid have shown that anatomically also the root formation goes by steps. First, a general meristem is formed, and in this meristem a further differentiation of root primordia takes place. It is not likely that the two successive reactions, described in this paper and leading towards root formation, can be identified with these two stages in anatomical differentiation. For one thing, the time relationships are very different. These observations, however, indicate that the physiological analysis can be carried much farther and that ultimately we may expect to find a long chain of reactions leading towards root formation, of which the two reactions which can be recognized are only two of the earlier links. This conclusion seems to be confirmed by the discovery of a great many factors involved in root formation (Went and Thimann, 1937).

A further comparison of growth and root forming reactions, and the bearing of these experiments on the problem of a master reaction induced by auxin, will be considered in another paper.

## SUMMARY

Etiolated pea stem cuttings were used as quantitative test objects for the root forming activity of different auxins. These peas are very suitable for such investigations, since they are relatively free of auxin. It was shown that phenyl acetic acid is not in itself a root forming substance.

If the period of auxin treatment is divided into two shorter ones, it is possible to separate two distinct portions of the effect of indole acetic acid in the formation of roots. The first phase of the auxin action is tentatively identified with redistribution of rhizocaline within the stem. This phase can be induced not only by indole acetic acid but also by phenyl acetic acid,  $\gamma$  phenyl butyric acid, sodium naphthol sulfonate, and other substances, not active in root formation proper. The second phase can be induced only by indole acetic acid and similar substances, and it has been suggested that this phase is the activation of the accumulated rhizocaline.

# THE RELATION OF COPPER AND ZINC SALTS TO LEAF STRUCTURE <sup>1</sup>

# H. S. Reed

Tomato leaves show characteristic deficiency symptoms when the plants are grown from the seed-ling stage in nutrient solutions lacking traces of copper or zinc salts. These symptoms consist of specific types of curvature of the rachis or of the leaflets, dwarfness, and ultimate necrosis of tissue of the leaf. The alterations due to deficiencies of these elements are quite distinct and will be discussed independently.

The purpose of this paper is to discuss certain histological characters of affected tomato leaves in relation to problems of nutrition and growth. The plants utilized were kindly furnished by Mr. P. R. Stout and Dr. D. I. Arnon, who have conducted experiments in which extremely refined methods were employed.

The technic of the cultures was essentially the same as that described by Arnon (1938) and will not be repeated here, except to say that the complete list of microelements furnished was: zinc, copper, boron, manganese, molybdenum, vanadium,

<sup>1</sup> Received for publication October 11, 1938.

titanium, tungsten, chromium, nickel, and cobalt. Further details of technic are given by Stout and Arnon (1939).

Forbes' (1917) study of the effects of copper salts in irrigating waters and soils gives a comprehensive view of the physiological problem. He demonstrated that the copper salts were absorbed by the roots and traced the channels through which they traversed the plants. When lethal concentrations of copper salts were present the first injury was in the root-tip, where the concentration of copper was many times greater than the other parts of the plants. Forbes also showed that, when sublethal concentrations of copper salts were present, the growth of plants was enhanced.

The effects of copper salts on leaves was observed originally in connection with the results of spraying plants with copper-lime fungicides. Rumm (1893) compared the tissues in sprayed and unsprayed grape leaves, finding differences in width so small that they cannot be regarded as significant. The palisade parenchyma cells of the sprayed

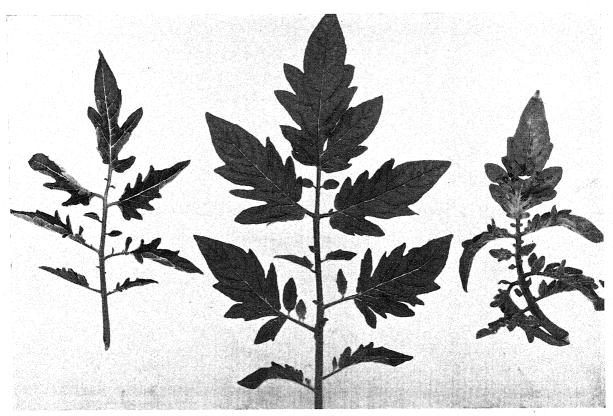

Fig. 1. Leaves of the same age from tomato plants grown in water cultures. From left to right the sources were: (a) complete nutrient solution with supplementary elements from which copper was excluded; (b) same with all supplementary elements present; (c) same with supplementary elements from which zinc was excluded. Photograph furnished by Dr. D. I. Arnon and Mr. P. R. Stout.

leaves, nevertheless, contained a greater number of chloroplasts, although their average size was somewhat smaller. The spongy parenchyma of sprayed leaves was more compact and also richer in chlorophyll.

Bain (1902) reported that the deposits of copper salts on leaves affected the formation of starch in the underlying tissues. Grape leaves showed the greatest benefit from copper sprays, apple leaves came next, and finally the peach, which is rarely benefited by spraying under normal conditions.

Bain made microscopical examinations of the leaves to determine the effect of the copper deposits on starch formation. When the leaves of seedling peach trees were sprayed with copper-containing liquids there was an irregular deposit of copper owing to the tendency to form droplets. Directly beneath these spots there was diminished starch formation both in the greenhouse and in the open. However, when sprayed leaves from trees in the open were examined, there was usually a halo of increased starch formation surrounding the spots especially of  $Cu(OH)_2$  and of  $Cu_3O_2(OH)_2$ .

It thus appears that with sufficient illumination the first effect of copper on the assimilative cells of the peach leaf, if not added in too great quantity, is to stimulate them to greater activity. Young leaves responded to the copper stimulus in less time than the older ones. There was a wide diffusion of the copper stimulus on the young leaves of peach and grape.

COPPER DEFICIENT LEAVES.—When one attempts to study the beneficial action of copper salts on the growth of seedling plants, it is necessary to use extremely refined methods. The salts and the water must be purified with especial care. Lipman and Mackinney (1931) showed that copper was essential for certain plants, but reported that the limit of impurity for each culture was less than 0.01 part per million of Cu.

Tomato plants began to show the effect of copper deficiency in a few weeks when grown under the refined technic employed by Stout and Arnon. The leaf shown at the left in figure 1 is from one of their cultures and shows how the axes and laminae were restricted in growth, although the number of leaflets and their lobes were not reduced. The midribs of the leaflets were not curved, but the laminae were characteristically involuted. The color of the leaflets at the time when the specimen was photographed was bluish-green, with a sheen very distinct from any other deficiency symptom yet discovered in the tomato.

In succeeding weeks necrotic areas appeared. The color of the young leaflets may be compared to the rich green color of citrus leaves in the early stages of exanthema.

The palisade cells of affected leaves were crowded with large plastids, confirming what was previously noted concerning the greenness of the leaf. The plastids contain starch grains and probably carry on normal photosynthesis. The plastids of young leaves were hyperchromatic, indicating that the first state of injury had already arrived. Moreover, these hyperchromatic plastids were surrounded by minute globular mitochondria.

Tomato leaflets bear stomata on both surfaces. Those on the dorsal surface are less numerous but larger than those on the ventral surface and are associated with cavities which are formed by the separation of the subjoined palisade cells. Relatively few of the dorsal stomata appear functional except during the early stages of their existence. The guard cells appear hypoplastic, and the majority of the stomata mentioned were filled by a mass of amorphous material.

The substomal cavities in the palisade parenchyma are initiated by a separation of the upper end of the palisade cells (fig. 2). In the same leaflet one may find advanced stages in the formation of these cavities in which the palisade cells are completely separated and the cavity still further widened by shrinkage in diameter of the cells adjoining the lacuna.

Tomato leaves from plants grown out of doors in a complete nutrient solution formed few stomata on the upper surfaces and there were no large substomatal cavities in the palisade parenchyma.

The formation of lacunae in leaflets of copperdeficient plants by the schizogenous process mentioned was followed by lysis of palisade cells, resulting in the formation of columniated parenchyma totally unlike that observed in plants from cultures lacking other essential elements (fig. 2).

The plastids of affected leaves were ultimately disorganized, evidence of which was shown by the development of pale stripes in the laminae along the veins, concomitant with an unthrifty condition of the plant. A microscopical examination of fresh sections of leaves showed that an extreme condition of hyperplasia existed. The palisade and spongy parenchyma cells did not generally accumulate neutral red in the vacuoles, but their nuclei were Spongy parenchyma cells had calcium oxalate crystals of the monohydrate type. plastids of all cells were in various stages of disorganization with a tendency to form clumps at one end of the cell. Most of them had lost their homogeneity due to the aggregation of the chlorophyll into small droplets which gave the plastids verrucose surfaces. The green pigment in the droplets was readily dissolved out by dilute sodium oleate or by dilute commercial liquid soap. The cell vacuoles after such treatments were completely filled with diffuse pale green pigment.

Tomato leaves in a more advanced stage of injury showed necrotic tissue. An examination of sections

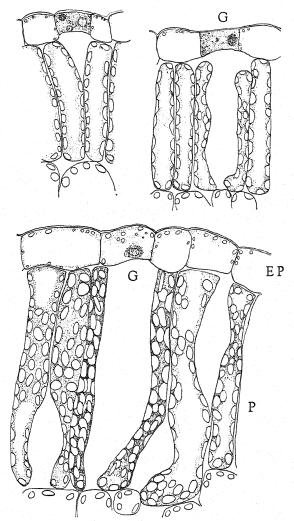

Fig. 2. Palisade parenchyma of tomato leaves to show successive stages in the formation of lacunae in copper-deficient plants. Drawings from fixed material stained with acid fuchsin and methyl green. The upper figures represent conditions in younger leaflets. The lower figure represents a condition characteristic of older leaflets. EP, epidermis; G, guard cell; P, palisade.

of fresh material showed that disorganization and collapse of cells started in the palisade parenchyma, usually in the vicinity of stomata, thence spreading to the spongy parenchyma where similar disintegration occurred, and finally the cells turned brown and dried out.

The copper content of orange leaves indicates that there may be some relation to exanthema, although soil and climatic conditions are also important factors (Haas and Quayle, 1935). Leaves from healthy trees contained about 15 parts per million copper, and leaves from affected trees in the same locality contained 7 parts per million.

Exanthema is often cured by the application of copper sulfate to the soil or to the trees, but the way in which it acts is not well understood. The

low copper content of affected pear leaves suggests that exanthema was due to a deficiency of copper (Oserkowsky and Thomas, 1933), yet healthy appearing leaves selected from trees which showed signs of the disease were no richer in copper than the affected leaves. However, normal leaves from localities free from the disease contained from two to four times as much copper as the typically exanthema leaves.

In early stages of exanthema the leaves are often dark green and appear healthy, but they are usually followed by leaves and shoots which are depauperate and short-lived. The leaves of affected orange trees are spotted with exuded gummy or resinous material. Fruits on affected trees fail to develop.

One cannot fail to be impressed by the importance of the function of copper in plant nutrition, although comparatively few physiological or cytological studies have been made. The principal attention thus far paid by plant biologists has been to the toxic effects of copper. It is evident that future investigations should have a broader scope than those of the last few decades.

ZINC DEFICIENT LEAVES.—Additional studies on the cytology of zinc-deficient tomato leaves were made on material furnished by Mr. Stout and Dr. Arnon. The leaf at the right in figure 1 shows acute symptoms of zinc deficiency, among the most prominent of which are: (a) dwarfness, (b) paleness, (c) downward curvatures of the leaflets, (d) involuted laminae, (e) dead spots on rachis and laminae.

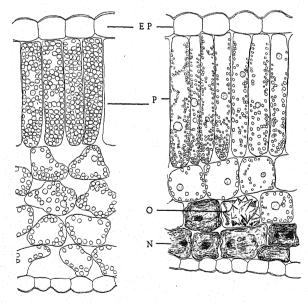

Fig. 3. Structure of tomato leaves drawn from fresh sections mounted in Ringer's solution. Left, a healthy leaf from a plant grown in nutrient solution containing all supplementary elements; right, a pale, dwarfed leaf from a plant grown in nutrient solution with supplementary elements from which zinc was excluded. EP, epidermis; N, necrotic cells; O, mass of calcium oxalate crystals; P, palisade.

These characteristic symptoms were produced also on tomato plants grown in a soil in which the little-leaf of fruit trees is found. It is important therefore to compare the histological structure of plants from Delhi soil with these which grew in nutrient solutions deficient in zinc.

The palisade parenchyma of affected tomato leaves grown in Delhi soil was greatly hypertrophied as a result of the striking elongation of the cells and contained relatively few plassids (Reed, 1938). The spongy parenchyma, on the contrary, was poorly developed and comparatively chlorotic. These histological characters have been noted in citrus and other leaves affected with little leaf symptoms (Reed and Dufrenoy, 1933).

The structure of healthy and affected tomato leaves from plants grown in nutrient solutions, therefore, have a general resemblance to those from soil, though the contrast is less pronounced. Figure 3 shows the structure of healthy and affected tomato leaves from plants grown in the nutrient solutions of purified salts previously mentioned. The drawings were made from fresh sections mounted in Ringer's solution, and the same scale of magnification was used throughout.

The palisade cells of the affected leaves were longer and narrower and the spongy parenchyma was more compact than that of the healthy leaf. Not more than one palisade cell in seven had the ability to accumulate neutral red in its vacuole, indicating a hypoplastic condition. The plastids contained fat globules, but there were no free globules in the cell vacuoles. The nuclei stained readily with methylene blue, even though the cell was notably disrupted.

The number and size of the plastids showed a contrast. Those of the palisade of the affected leaf were small and had a tendency to accumulate at the lower end of the cell. Those of the healthy leaf were larger, contained starch grains instead of fat globules, and were uniformly distributed in the parietal cytoplasm. In affected leaves where the processes of disintegration had been operative, the number as well as the size of the plastids was greatly reduced, producing pale or mottled leaves which are characteristic of zinc deficiency conditions.

It is important to notice how intimately the production of chloroplasts is related to the presence of zinc salts in practically every plant thus far examined. Iron salts are also important, but in none of the cases examined was their presence a limiting factor for chlorophyll production. Mottled orange leaves (to cite one example) contain as much iron as healthy leaves. The addition of iron does not ameliorate the condition.

The most conspicuous indications of degeneration in the tomato leaf were in the spongy parenchyma, where more of the cells contained aggregations of calcium oxalate crystals than those of healthy leaves. In this layer the first signs of necrosis were found, consisting of shrinkage and formation

of a melanotic substance which obscured the details of the cell structure (fig. 3). The necrosis advanced from the spongy parenchyma, ultimately reaching the dorsal surface and producing the brown spots previously mentioned. Toluylene blue penetrated readily and stained the degenerated cells of the spongy parenchyma but did not penetrate the palisade cells until they were dead. In affected orange leaves the formation of calcium oxalate was a forerunner of phloem necrosis, and it may indicate an incomplete utilization of carbohydrates (Reed and Dufrenoy, 1935).

The degeneration of tomato leaves showing zinc deficiency starts in the spongy parenchyma in contrast to the degeneration of the palisade layer in copper deficient leaves described above.

Plants in purified nutrient solutions showed necrosis of the rachis of the leaves after a time. In the first well defined stages the necrosis was restricted to the chlorophyll-bearing cells situated inside the epidermis. In later stages the deeper layers of the rachis were necrotic. The affected cells contained tannin (reaction with ferric chloride or potassium bichromate). The epidermal cells showed no injuries until after the hypodermal layers had collapsed. The hypodermal and collenchyma cells had no capacity for storage of neutral red. Collapse of the hypodermal cells was due

to weakening of the radial walls and destruction of cellulose.

### SUMMARY

Tomato plants grown in copper-deficient nutrient solutions showed characteristic dwarfing, involution of the leaflets, color change, and eventual necrosis. At an early stage substomal cavities were formed, resulting from the separation of palisade cells. Subsequently the separated palisade cells shrunk and ultimately disappeared as a result of the lysis of the contents, producing columniated palisade tissue. If necrosis appeared, it started in these schizogenous cavities.

Tomato plants grown in zinc-deficient nutrient solutions showed characteristic dwarfing, curvature of leaflets, chlorotic leaflets, and involuted laminae in which severe necrosis appeared early. The palisade cells were longer and the spongy parenchyma was more compact than in similar leaves from healthy plants to which zinc had been supplied. The plastids were small and contained oil drops, but there were no free oil globules in the vacuoles. Conspicuous signs of disrupted metabolism were seen in the spongy parenchyma, identifiable as scarcity of plastids, production of melanotic material, and abundance of calcium oxalate crystals.

# CULTURE STUDIES OF MARINE ALGAE. I. EISENIA ARBOREA <sup>1</sup>

George J. Hollenberg

EISENIA IS a typical member of the Laminariales. As stated by Setchell and Gardner (1925), there are two well recognized species in the genus, E. arborea Areschoug, the type species, found along the coast of southern California, and E. bicyclis (Kjellm.) Setchell, found in Japanese water. Setchell and Gardner do not mention E. Cokeri, described by Howe (1914) from the coast of Peru, where it is reported as very abundant. I have not examined specimens of E. Cokeri. Howe states that the plant is very similar to E. arborea, but that the stipe is longer in the Peruvian plant, and that the sporophylls are "longitudinally rather than reticulately rugose." My observations indicate that the stipes of typical plants of E. arborea are fully as long as measurements given by Howe for E. Cokeri. Furthermore, the sporophylls of E. arborea are decidedly longitudinally rugose or corrugated in most cases. In fact, Howe's figures (Plate 14A, 15, 16) represent a plant essentially identical with those found along the coast of southern California. Howe states that the most distinctive feature of E. Cokeri is the almost complete lack of muciferous canals in the stipe. These structures are usually very abundant in E. arborea, forming a macroscopically visible ring near the outer margin of the stipe as seen in cross section. This is the only difference which I can discover between Eisenia Cokeri as figured and described by Howe and the southern California plant. It seems doubtful, therefore, if E. Cokeri should be considered as a distinct species.

Eisenia (?) Masonii described by Setchell and Gardner from the Revillagigedo Islands off the west coast of Mexico is a doubtful member of the genus.

Eisenia arborea was first described by Areschoug in 1876. It is very common at low tide level on rocky shores along the coast of southern California, mostly south of Redondo Beach. The sporophyte is well described by Setchell and Gardner (1925). It is commonly 12-14 decimeters long, and is frequently 15 decimeters or more in length. In one case the stipe alone measured 15 decimeters. Clare and Herbst (1938, p. 494) state that the plant is "usually one-half to three-fourths of a meter in They may have had reference to measurements given by Setchell and Gardner (1925), who state that the stipe is commonly 1 meter long. At any rate, the statement of Clare and Herbst is very misleading, especially when accompanied by a photograph of a plant with an unusually short stipe.

Setchell (1905) has described the post-embryonal development of the sporophyte of *Eisenia arborea* in which it passes successively through stages in which it assumes the aspect of a *Laminaria* and later of an *Ecklonia* with lateral pinnae before it develops the characteristic features of *Eisenia*.

<sup>1</sup> Received for publication November 7, 1938.

Post-embryonal stages of *Eisenia bicyclis* as described and figured by Okamura (1927, p. 140-143, pl. 238) are very similar to those of *E. arborea*.

Numerous collections of fruiting sporophytes have been made at all seasons of the year during the past four years. The normal fruiting period seems to be from about May to December. Vigorous cultures have been started from plants collected as early as June and as late as December. From January to May only occasional remnants of old sori are usually to be found.

The sporophylls are linear and mostly unbranched, but forked sporophylls are frequently encountered. The sporophylls are narrowed at the base and rounded at the apex. The margin is usually beset with a series of low teeth, but is frequently nearly smooth. Marginal proliferations are more rarely present. Any or all of the leaflets may function as sporophylls when mature. The sori are elongate patches, typically covering both sides of the basal third or more of the sporophyll, except for a narrow sterile strip along the margin. In old sporophylls the sorus may be limited to an area some distance from the base. The latter condition apparently results from the activity of a meristematic region at the base of the sporophyll and the erosion of the tip. The sori are frequently irregular in outline or even composed of discontinuous patches, but I am unable to agree with the statement of Clare and Herbst (1938) that the sori first appear as irregular patches which later fuse. My observations indicate that the sori are typically entire and continuous from the beginning. The maturity of the sori may be roughly judged by the depth of color. Fully mature sori are dark in color and more mucilaginous when handled, especially some time after removal from the water.

Ikari (1926) made culture studies of Eisenia bicyclis. He showed that the life cycle is in general much like that previously described for other members of the order. He does not give many details concerning the gametophyte generation. However his findings are in close agreement with those here reported for E. arborea.

Culture studies of Eisenia arborea have been in progress for the past four years. As this paper neared completion there appeared an article in this Journal by Clare and Herbst (1938) which deals with culture studies of Eisenia arborea. These investigators fail to mention the work of Ikari. Their observations were based entirely on living material. The study here reported includes a cytological investigation of critical stages in the life cycle. This report differs, furthermore, in a number of important respects from the findings of Clare and Herbst and includes items either overlooked or unobserved by them.

CULTURE METHODS.—Large Petri dishes and glass stacking dishes 4 cm. high and 12 cm. in

diameter were employed with nearly equal success. There is reason to believe that the cultures receive a better supply of oxygen in shallow containers. Culture solutions were composed of sterile sea water to which was added small amounts of NaNO3 and Na<sub>2</sub>HPO<sub>4</sub> as recommended by Schreiber (1930) and other investigators. Most investigators have reported temperatures of 10-12°C. as necessary or most favorable for the culture of germling stages of Phaeophyceae. Kanda (1938) and a few other investigators have cultured germlings of Laminariales at ordinary room temperatures. In the case of Eisenia arborea an abundance of fruiting gametophytes and young sporophytes developed in cultures at ordinary room temperatures (mostly 17-22°C.). Cultures kept at lower temperatures developed more slowly and less vigorously. They did not fruit as readily nor as vigorously. In view of the fact that I have also been able to culture germlings of several other brown algae at room temperatures, it seems possible that the importance of low temperatures may have been over-emphasized in some instances by previous investigators. However, most investigators of germling stages in the Laminariales have dealt with plants adapted to relatively low temperatures. In southern California the surface temperature of the ocean along the shore varies mostly around 14-17°C. It seems likely that the temperature to which Eisenia arborea is accustomed in nature may account for the readiness with which the sexual plants developed at relatively high temperatures in the cultures. The cultures were kept in a well lighted room with northern light exposure.

Mature fruiting sporophylls were kept out of water from 1 to several hours with some precautions taken to prevent excessive drying. Three or 4 small pieces were quickly but thoroughly washed in sterile sea water and then placed in a small amount of nutrient solution for 2-3 minutes. In the case of many brown algae, especially members of the Laminariales, this is sufficient time for the discharge of mature spores if fully mature fruiting portions have been selected. The pieces were then removed and a few cubic centimeters of the nutrient solution, containing great numbers of motile spores, were transferred, by means of a pipette, to other dishes containing about 100 cc. of nutrient solution and several glass slides.

Clare and Herbst (1938) and a number of other investigators have followed a practice of leaving bits of fruiting sporophylls in the nutrient solution in the culture dishes for 12-24 hours. This is entirely unnecessary and undesirable in the case of many brown algae, and it is certainly so in the case of Eisenia. This procedure apparently accounts for some of the difficulties these investigators have experienced, especially in studying motility of the zoöspores and in keeping the cultures free from contamination. Clare and Herbst report placing "10 to 12 fragments of sori about 1 centimeter square" in each culture dish. My experience indi-

cates that if fully mature sori are used, this procedure would most certainly result in overcrowding of the cultures. It is well known, moreover, that copious quantities of mucilaginous material are liberated from even small pieces of many different members of the Phaeophyceae when such pieces are left standing for even a short period of time in water. This mucilaginous material undoubtedly encourages the development of bacteria and perhaps other undesirable inhabitants of the cultures. Even with the best of precautions, however, it is very difficult to get cultures altogether free from diatoms. Chytrids also frequently infect the cultures. I have several times obtained vigorous cultures of germlings in which I was unable to detect a single diatom, but these cultures never fruited. It is doubtful if their failure to fruit is of any special significance since other cultures with diatoms present also failed to bear sex organs. It is of interest to note in this connection, however, that Angst (1927) observed that those cultures of Costaria containing infusoria made the most rapid progress.

Development of sporangia.—Small portions of sori from freshly collected plants and in various stages of development were fixed in a solution composed of 1 gm. of chromic acid and 1 cc. of glacial acetic acid per 100 cc. of sea water. N-butyl alcohol was employed in dehydrating and embedding, and sections  $4\mu$  thick were made in the usual manner and stained with Heidenhain's iron-alum-haematoxylin.

In sterile portions the cortex is composed of 1 or 2 rows of small cells, the cells of the outer layer being somewhat elongated perpendicular to the surface of the blade. In the development of fruiting areas the cells of the outer layer divide, usually slightly obliquely, forming an outer cell, which is still somewhat elongated vertically, and a smaller, more or less isodiametric inner cell. The outer cell contains 5 or more chromatophores and a single nucleus. It is destined to become a paraphysis. Its outer wall very early begins to thicken (fig. 2) to form the so-called hyaline appendage typical of the paraphyses of the Laminariales. The inner cells each contain a single nucleus and 2-3 or occasionally 4 chromatophores. These cells each give rise to a sporangium. The nucleus enlarges considerably and divides (fig. 1). During this division about 30 minute chromosomes are visible. One daughter nucleus migrates into a small protrusion which has meanwhile developed outwardly between adjacent young paraphyses (fig. 1) and into which a single chromatophore has previously migrated. A cross wall develops, and the chromatophore of the resulting sporangial cell divides to form several chromatophores. At the same time, the nucleus enlarges greatly and undergoes typical meiotic stages (fig. 3-5). Synaptic union reveals the presence of 15 pairs of minute chromosomes (fig. 5). In early meiotic stages the chromosomes are elongate and present the appearance of a typical spireme. Each apparently shortens during synapsis to form a spherical or slightly elongate body. The two nu-

clei resulting from the first division of this primary nucleus contain the haploid number of chromosomes (fig. 6). I have also been able to distinguish about 15 chromosomes in the nuclei of a fournucleate sporangium. Following the first nuclear division, all subsequent nuclear divisions in a given sporangium are simultaneous. By the time 16 nuclei have been formed it becomes apparent that the number and position of the chromatophores correspond closely to that of the nuclei, each chromatophore being closely associated with a single nucleus (fig. 6) and dividing with it, as reported by McKay (1933) for Pterygophora. As the sporangia approach maturity, numerous small vacuoles about 0.5 \( \mu \) in diameter appear in the cytoplasm between the nuclei. The individual zoospores are soon delimited, apparently by fusion of these vacuoles. In mature sori the paraphyses are unicellular and contain several chromatophores and a single nucleus. The tip of the cell is often filled with a dense protoplasmic mass below which are the chromatophores. As the sorus reaches maturity, the cuticle covering the tip of the paraphyses loosens and is shed. Mature sporangia measure 45-60  $\times$  12-15  $\mu$  and appear to contain approximately 32 or 64 spores. I find no evidence that the contents of mature sporangia draw away from the wall as reported by Clare and Herbst. The wall at the tip swells greatly (fig. 7) as the sporangium reaches maturity, and eventually ruptures to release the spores. New sporangia are continually arising at the base of old ones from the same supporting cells, and it seems probable that a given sorus continues to shed spores for some weeks at least.

Zoöspores.—Clare and Herbst (1938) report that they were unable to detect flagella on the zoöspores or any evidence of motility. They state that the spores "emerge and float away." They furthermore state that the spores float for 12-24 hours before becoming attached. These statements and conclusions seem to be very much in error. Their inability to detect motility of the zoöspores or to see the flagella would appear to be due to faulty technique in starting cultures, or as I have already suggested, to the use of immature sori, or perhaps to both. I have obtained vigorous swarms of very active spores some 20 or more different times. There is, moreover, not the least difficulty in seeing the two flagella. These are readily visible without resort to staining. In fact, some staining procedures will quickly cause the zoöspores to shed their flagella. In this connection one is also inclined to question the findings of Herbst and Johnstone (1937), who report their inability to find flagella

or evidence of motility of zoöspores in the case of Pelagophycus porra (Leman) Setchell.

The zoöspores of Eisenia arborea (fig. 8) are of the usual form, slenderly pyriform, 6-9 μ long and 3-4.5 \mu in diameter, with two lateral flagella inserted somewhat nearer the anterior end. The forwardly directed flagellum is, as usual, the longer and more active. It is at least twice the length of the cell. The posteriorly directed flagellum is only slightly longer than the cell and is practically motionless while the swarmer is motile, but it may at times exhibit movement. A single chromatophore occupies the posterior third or more of the cell; the anterior end is hvaline. A stigma is definitely present in the form of a more or less elongated body associated with the chromatophore on one side of the cell. The figures of Ikari (1926) show that the zoöspores of Eisenia bicyclis are very similar to those of E. arborea. According to a translation of his paper. Ikari reports the absence of a stigma in the motile spores of E. bicyclis, and none is included in his figure of the spores. Kanda (1936, 1938) reports the absence of a stigma in the zoospores of a number of Laminariales which he studied. He furthermore states that the stigma has been previously reported as present in the zoöspores of only three members of the order: namely in Laminaria religiosa, reported by Ikari (1921); in Egregia Menziesii, reported by Myers (1928); and in Pterygophora californica, reported by McKay (1933). In addition, Kanda (1938) reports having observed a stigma in the zoospores of Chorda filum (L.) Lam'x. In spite of the presence of a stigma in the zoöspores of Eisenia arborea I have been unable to detect any special phototactic response on the part of the swarmers.

GAMETOPHYTES.—Within a few hours, and usually within an hour or so after liberation, the swarmers come to rest, lose their flagella, and become round in outline. Secretion of a wall soon attaches them to the substrate. Germination of the spore is very much like that previously described for other members of the Laminariales. Under favorable conditions a germ tube (fig. 9) is formed within 8-12 hours, but its formation may be delayed as much as 20-30 hours. The tip of the tube swells, and most of the protoplasm migrates into the swollen tip (fig. 10) and is cut off from the original spore case by a cross wall in a manner characteristic of the order. This occurs when the germlings are 36 hours to a few days old. There follows a period of increase in the size of the cell (fig. 11) and in the number of chromatophores—a developmental phase which Harries (1932) and other investigators speak of as a temporary resting period. A short filament

is soon formed by cell division. It usually grows laterally in opposite directions from the original proembryo (fig. 12). Although the germ tubes do not exhibit any noticeable phototropic response, the first formed filaments of the gametophytes show a distinct positive phototropic growth in moderate light intensities. This usually results in a unilateral branching of the gametophytes (fig. 13, 15). Under favorable conditions, male and female plants are distinguishable about 15 days after germination. The male plants are conspicuously smaller and, as in other members of the order, considerably more branched than the female plants. An entire culture will frequently develop into very elongate, branched filaments with few or no sex organs. This condition is interpreted as one favorable for growth but unfavorable for reproduction. Harries (1932), working with Laminaria digitata, reports that nutrient conditions most favorable for growth are also most favorable for the production of sex organs. She indicates, however, that high temperature, intense light, or an excessive amount of phosphates induces development of an elongate type of gametophyte. Schreiber (1930) reports that cultures of germlings of Laminaria, which were sterile at higher temperatures, were induced to fruit by placing them in a refrigerator at 2-4°C. When gametophytes of Eisenia arborea in the cultures once take on an elongate sterile form, I have been unable to induce the formation of sex organs, although I have tried low temperatures (2-3°C.) and changes in light intensity as well as changes in nutrient concentra-

Fruiting female fllaments measure  $11-14~\mu$  in diameter. This is somewhat larger than measurements given in the case of gametophytes of most other members of the order, but corresponds closely to measurements given by Ikari (1926) for gametophytes of Eisenia bicyclis. Clare and Herbst (1938) give no measurements of mature gametophytes. Female gametophytes of Eisenia arborea are frequently unbranched and composed of relatively few cells, but they are also frequently composed of numerous cells and bear one to several branches. The cells are mostly 1.5-3 diameters long. Male filaments are usually  $6-8~\mu$  in diameter with cells of a corresponding length.

Development of antheridia.—Antheridia in the Laminariales were first observed by Sauvageau (1915), who described them as developing in clusters at the tips of the branches of the male filaments. This characterization has been accepted ever since with but little modification in most descriptions of antheridia in the order. In some cases it seems evident that antheridia were either not seen or were not carefully studied. The photomicrograph of so-called antheridia published by Clare and Herbst (1938, fig. 3) for Eisenia arborea is certainly open to question. One is inclined to wonder if these investigators may not have observed male filaments with terminal branches infected with chytrids, since they state, as have some other investigators, that

any cell may function as an antheridium and that the filaments become "invisible" soon after discharge of the gametes.

I have studied antheridial development of Eisenia arborea, both in living cultures and in stained slides. In vigorous cultures they first appear about 40 days after germination of the spores. The nucleus of a cell of a filament divides and one of the daughter nuclei migrates into a short protrusion of the cell. It is then cut off by a cell wall which divides the cell obliquely (fig. 16, 17) or separates the protrusion at the base from the parent cell. In either case the daughter cell receives a number of chromatophores. It may function as an antheridium or it may be the initial cell of a very short branchlet which produces one or more antheridial outgrowths at its apex. As a result, the more or less conical antheridia are sessile either on the branches or on very short 1-2-celled branchlets. They arise in clusters of 2-3 or more on a given cell. New ones may form after older ones on the same branchlet have discharged their antherozoids. In vigorous cultures the antheridia are not at all limited to the tips of the branches as reported by Clare and Herbst (1938) but may extend the entire length of the branches (fig. 14). Harries (1932) states that in Laminaria digitata "any cell may function as an antheridium, the end cells being first converted." Herbst and Johnstone (1937) and Clare and Herbst (1938) use nearly the same words in describing the antheridia of Pelagophycus porra and Eisenia arborea, respectively. These statements give the impression that the antheridia consist of the transformed terminal cells of the filaments, resembling in origin a uniscriate plurilocular sporangium. This is contrary to the descriptions and figures given by most investigators, and it is certainly not the case in Eisenia arborea. My observations indicate that the cells of the branches giving rise to antheridia may lose their contents following the discharge of the antherozoids, but no evidence was obtained which would indicate that the cells of the branches function as antheridia or are converted into antheridia. In the case of very short lateral branchlets a cell of the branchlet is occasionally found to be continuous with an empty antheridium (fig. 16), suggesting that a cross wall failed to form at the base of the antheridial outgrowth.

As the antheridium nears maturity, the wall at the tip becomes greatly thickened. When fully mature, this thickening consists of a nearly spherical globule of gelatinized wall material (fig. 16). This spherical cap evidently becomes loosened as the result of a transverse rupture encircling the base of the plug or cap, and the antherozoid is released, leaving the tip of the antheridium open.

ANTHEROZOIDS.—All evidence indicates that in the Laminariales each antheridium produces but a single antherozoid, although the liberation of the antherozoid has been seen by only a few investigators. McKay (1933) studying Pterygophora, gives

the first good description of male gametes of the Laminariales, although Williams (1921) had previously observed the liberation of these motile cells in Laminaria. I have not been fortunate enough to see the antherozoids discharged from the antheridia and hence cannot be certain that a number of small motile cells with two lateral flagella of nearly equal length and a number of very pale chromatophores, which were seen in the cultures, were male gametes of Eisenia. It is believed that they were. However, in stained slides of fertile gametophytes I have been able to find cases of single antherozoids killed just after extrusion, while still in contact with the tip of the antheridium (fig. 18). Furthermore, in living plants I have observed, in each of a number of undischarged antheridia, a single minute reddish stigma, and in stained slides antheridia always contain but a single nucleus. These observations indicate rather definitely that but a single antherozoid develops in each antheridium. It is of interest to note that Kanda (1936, 1938) reports the absence of a stigma in the antherozoids of several members of the Laminariales which he studied.

Sauvageau (1916) thought he observed two small pale chromatophores in the antheridium of a species of Laminaria. Most investigators have either concluded that there is but a single chromatophore or are silent on this point. Kanda (1938) observed antheridia and antherozoids of a number of Japanese members of the Laminariales. He states that some of the apical cells of the male filaments become antheridia and that most of the chromatophores disintegrate as the antherozoid is formed. He thus indicates that there are several chromatophores in the antheridium when first formed. As I have previously indicated, the antheridia of Eisenia arborea are not to be considered as transformed terminal cells of the filaments. Nevertheless, the antheridia seem to contain a number of chromatophores at the time of their formation, although these are pale and indistinct. In mature undischarged antheridia and in discharged antherozoids stained slides likewise reveal the presence of a number of chromatophores (fig. 18). Finally, during stages in the fusion of the antherozoid with the egg (fig. 22-25), a number of chromatophores are distinctly visible in the antherozoid. It seems evident, therefore, that in the case of Eisenia arborea the chromatophores in the antheridia do not disintegrate as reported by Kanda for certain members of the order.

Formation of oögonia.—Female gametophytes arrive at sexual maturity 40-50 days after zoöspore germination in vigorous cultures. As in other members of the order, any cell of the filaments may develop into an oögonium. A terminal cell may simply elongate, but in the case of an intercalary cell a lateral extension develops which is commonly eight or more diameters long (fig. 15, 19, 20). No cross wall is formed, but the nucleus of the cell enlarges greatly and migrates into the extended portion where it takes a position near the center of the oögonium or somewhat nearer the tip. There

is a considerable increase in the number of chromatophores which are mostly peripherally arranged. The center of the oögonium is filled with a large vacuole with numerous strands of cytoplasm in which a number of dark-staining granules are usually visible (fig. 19, 20). The chromatophores may become more elongate in form and in living plants appear paler as in the case of chromatophores in the antheridia, but no evidence was obtained which would indicate that they disintegrate as reported by Kanda (1936, 1938) for several members of the order. Kanda seems to have made his observations from living material only.

McKay (1933) observed a noticeable thickening of the apex of the oögonium before liberation of the egg in the case of Pterygophora californica. Clare and Herbst (1938) report a similar thickening at the tip of the oögonium of Eisenia arborea, but they failed to note an interesting feature usually characteristic of this terminal thickening. I refer to the appearance of numerous papillae, which are frequently rather long and conspicuous (fig. 19, 20) and which form a sort of cap covering the tip of the oögonium. These papillae probably represent local points of gelatinization of the wall. Stained preparations show that, as this cap weakens by gelatinization, it may stretch greatly to form a temporary thin veil over the extruded egg (fig. 21). More frequently it appears to loosen as the result of a transverse rupture, in which case a fragmentary thin cap may be carried outward by the egg as it emerges (fig. 26). Finally, the egg frequently emerges through a more or less longitudinal rupture in the gelatinized papillate cap at the tip of the oögonium

I am of the opinion that extrusion of the egg takes place in a relatively short period of time. Partially extruded eggs are very rarely found in stained preparations showing numerous seemingly mature oögonia and numerous extruded eggs. It seems probable that extrusion is initiated by turgor in the oögonium. Surface tension on the part of the protoplast would seem to account for the final stages in the withdrawal and rounding up of the egg at the tip of the oögonium. A small amount of cytoplasm and a few chromatophores are frequently

left in the oögonium.

Fertilization.—Most investigators have concluded that in the Laminariales the egg is not fertilized until after it is discharged. Stained slides of fertile gametophytes of Eisenia arborea show numerous stages in the development of the oögonium and the subsequent release of the egg and fusion of the antherozoid with the egg. These stages clearly show that the egg is fertilized at the tip of the oögonium after its discharge. When first discharged the egg is a spherical, naked mass of cytoplasm about 18  $\mu$  in diameter with a single large nucleus and numerous chromatophores (fig. 21, 22). The antherozoid appears to establish contact at its anterior end, probably somewhat laterally, where a slender protoplasmic bridge is formed between the

gametes (fig. 22). As this bridge widens, both gametes enlarge noticeably (fig. 23, 24). The increase in size is first evident in the antherozoid and appears to result from a migration of vacuolar sap from the egg into the antherozoid. This may be due to a difference in cytoplasmic density on the part of the protoplasts. The chromatophores of the antherozoid, at first smaller than those of the egg, seem to increase in size along with the increase in volume of the antherozoid. One is inclined to wonder if this considerable increase in volume on the part of the antherozoid is altogether normal. However, I have observed a number of instances of it, and in all cases nuclear stages indicated a normal progress in the process of fertilization. The oöspore averages about one-fourth greater in diameter than the unfertilized egg. The increase in volume appears to be due largely to an intake of water. After the male nucleus passes through the protoplasmic bridge, the antherozoidal bulge is gradually absorbed (fig. 25), and at the time of complete union of the sexual nuclei it is completely obliterated. Early in the process of fusion the egg begins to present a more clear-cut outline, and after fusion is completed, a cell wall is distinguishable.

Williams (1921) reports having observed stages in the union of the sexual nuclei of Laminaria, but his description does not indicate the fate of the cytoplasm and the chromatophores of the antherozoid. The figures and descriptions given by McKay (1933) for Pterygophora indicate that the cytoplasm of the antherozoid fuses with the egg. As shown by the foregoing account, this is definitely

the case in Eisenia arborea.

Early in the process of union of the gametes approximately 15 minute chromosomes are visible in the nucleus of the antherozoid (fig. 23). A similar number appears in the egg nucleus after the male nucleus passes through the protoplasmic bridge between the gametes and approaches the female nucleus (fig. 25). McKay (1933) figures the sexual nuclei of Pterygophora fusing in interphase. My observations show that in Eisenia arborea the chromosome complement of both nuclei is visible at the time of their union to form the zygote nucleus (fig. 25). The zygote nucleus apparently goes into a resting condition before dividing to initiate sporophyte development.

Embryo sporophytes.—In the cultures the eggs almost invariably remain in contact with the tip of the oögonium, where they develop into embryo sporophytes (fig. 15). Clare and Herbst (1938) mention two modes of development of embryo sporophytes. I have examined hundreds of these young sporophytes in various stages of development, and find no reason for distinguishing two methods of development. The short broad sporophyte figured by Clare and Herbst (1938, fig. 5) in my opinion represents a stunted developmental condition. The zygote ordinarily elongates and divides transversely several times to form a monosiphonous filament, which is usually 6–8 cells long and frequently con-

siderably longer, before longitudinal divisions are initiated at the apical end. Rhizoids begin to form from the basal cells when sporophytes are about 4 cells wide (fig. 29). A small amount of cytoplasm containing several chromatophores is frequently present at the tip of young rhizoids as described and figured by Kanda (1938) for Chorda filum (L.) Lam'x., but there are no septa in the rhizoids of Eisenia arborea as reported and figured by Kanda for Chorda. The sporophytes of Eisenia arborea remain monostromatic until many cells wide.

CHROMOSOME NUMBER AND ALTERNATION OF GEN-ERATIONS.—Kylin (1918) first showed for Chorda that meiosis occurs in the first nuclear division of the sporangium. He found a haploid number of 20 chromosomes. Myers (1928), working with Egregia Menziesii, describes reduction division in the first nuclear division of the sporangium and reports a haploid chromosome number of 8. McKay (1933) reports a haploid chromosome number of 13 in the case of Pterygophora californica, with meiosis occurring in connection with the first nuclear division of the sporangium. In Eisenia arborea, as has already been stated, meiosis likewise occurs in the first nuclear division in the sporangium. Fifteen pairs of small chromosomes are visible at diakinesis. I have also been able to distinguish about 15 chromosomes in the nuclei of the vegetative cells of gametophytes (fig. 11). The nucleus of the antherozoid and that of the egg each contain a similar number. Finally, in a two-celled sporophyte embryo approximately 30 minute chromosomes are distinguishable (fig. 28), and a similar number was found to be present in the nuclei of cells from which sporangia are cut off. It is evident, therefore, that in Eisenia arborea a cytological alternation of diploid and haploid phases accompanies the morphological alternation of a macroscopic sporophyte with a microscopic gametophyte and that the life cycle is that of a diplohaplont.

## SUMMARY

The life cycle and the gametophyte plants of Eisenia arborea are essentially like those described for other members of the Laminariales.

Low temperatures are not essential for culturing the sexual plants, which develop and fruit abundantly at ordinary room temperatures of 17-22°C.

Contrary to the findings of certain investigators, the zoöspores are motile and similar to those of other members of the order.

Antheridia are borne in clusters on any cell of the male filaments but do not arise by transformation of the cells of the filaments. The tips of mature oögonia usually become much thickened and covered with numerous papillae.

Antherozoids contain a number of delicate chromatophores rather than one, as generally described for other members of the order. These chromatophores do not disintegrate but are most evident at the time of fertilization.

In fertilization the cytoplasm and chromatophores of the antherozoid are incorporated in the fertilized egg.

The spores and gametophytes of Eisenia are haploid, meiosis occurring during the first nuclear

division of the sporangium. The sporophyte plant is diploid. *Eisenia* is a diplohaplont with a haploid chromosome number of 15.

# CYTOLOGICAL STUDIES ON THE HEPATICAE. II. THE NUCLEOLUS-CHROMO-SOME IN PALLAVICINIA LYELLII 1

# G. B. Wolcott

Each late telophase nucleus in developing sporophytes of Pallavicinia Lyellii (Hook) Gray contain two nucleoli (rarely one), two hetero-pycnotic chromosomes, and small bits of hetero-pynotic chromatin. These bodies are usually so arranged that one daughter nucleus is a mirror image of the other (fig. 2, 6). The number of such symmetrical nuclei is so large as to exclude any possibility of a chance determination of the location of the nucleoli. These observations have indicated that the nucleolus in Pallavicinia, as in Zea (McClintock, 1934), Vicia (Heitz, 1931), and other plants is associated with a particular chromosome. An investigation of nucleolar origin, behavior, and relationship to chromosomes was undertaken.

MATERIALS AND METHODS.—Pallavicinia was collected near Charlottesville, Virginia. Young sporo-

<sup>1</sup> Received for publication November 7, 1938. This study was made at the University of Virginia and at the Mountain Lake Biological Station. I wish to express my appreciation to Dr. Ivey F. Lewis for supervision of the work.

phytes and the meristematic regions of gametophytes were fixed in the following fluids: Taylor's (McClung, 1937), "Craf" (Randolph, 1935), and Lewitsky's (Lewitsky, 1931). The best results were obtained with Taylor's fixative. The material was sectioned at 10 microns and stained in gentian violet (Smith, 1934) and in gentian violet-safranin (Stockwell, 1934). Wratten filters, appropriate to the stain of the preparations, were used. The slides containing figures 14-16 and 18 were later destained and subjected to the Feulgen reaction. This treatment did not alter the appearance of the images.

Observations.—Early telophase stages (fig. 1) are completely devoid of visible nucleolar material. The nucleolus is first seen as a small globular mass during mid-telophase. Figures 3, 4, and 5 are polar views of sporophytic telophase nuclei during the expansion of the chromosomes to form the resting-stage reticulum. In each nucleus are two small nucleoli attached to, or arising from, the end of a

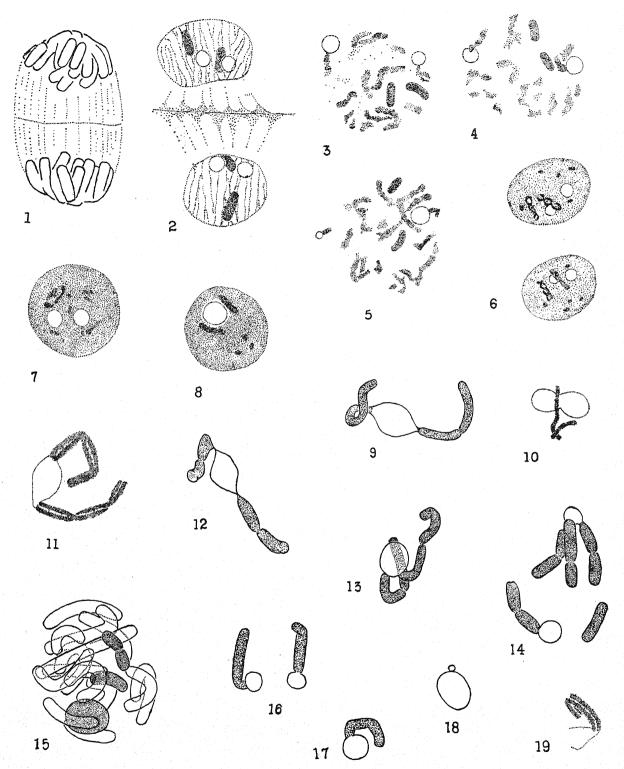

Fig. 1-19. All figures were drawn with the aid of a Zeiss camera lucida and at a magnification of  $3550 \times$ . Figure 17 is from a gametophytic nucleus; all other figures are from sporophytic tissue.—Fig. 1, 2, 6. Daughter nuclei in telophase. Note mirror-image arrangement of elements.—Fig. 3, 4, 5. Polar views of telophase nuclei with nucleoli forming.—Fig. 7. Resting nucleus with two nucleoli.—Fig. 8. Resting nucleus with a single fusion-nucleolus.—Fig. 9, 11, 12, 13. Prophase nucleoli, each with two attached chromosomes.—Fig. 10. Two nucleoli fusing in prophase.—Fig. 14, 16. Unfused nucleoli from late prophase, each with an attached chromosome.—Fig. 15. Late prophase with the full complement of chromosomes and the nucleolus unattached.—Fig. 17. Prophase nucleolus and attached chromosomes.

chromosome. The nucleolus at the left in figure 5 was faintly stained and may be considered as an incipient nucleolus.

As the nuclear membrane is formed during late telophases the nucleoli enlarge. Two daughter nuclei with fully formed membranes but with traces of the spindle still present are shown in figure 2. Figure 6 is a drawing of a later stage in which the spindle has disappeared. At this stage, in resting nuclei (fig. 7), and during early prophases no connection between the nucleolus and any of the chromosomes was visible, though faintly chromatic threads could be seen apparently attached to the nucleolus. The chromosomes are so finely drawn out that reliable interpretations of such a phenomenon are impossible.

As indicated, each nucleolus arises at the end of a chromosome; there are usually two in diploid telophases and never more than one in haplaid nuclei. In resting stages and prophases in sporophytes, however, many nuclei each with a single nucleolus are found (fig. 8). These nucleoli arise from a fusion of the two single nucleoli and are larger. The fusion of two nucleoli in a prophase nucleus is shown in figure 10.

Since, in telophase, each nucleolus is first seen in connection with a single chromosome (fig. 3-5), a fusion nucleolus should have two chromosomes associated with it. Such a condition is shown in figures 9, 11, 12, and 13 from prophase nuclei. The chromosomes are usually attached at opposite sides (or ends) of the nucleolus (fig. 9, 11, 12) but may also be attached adjacently (fig. 13). A few nuclei were found in which nucleoli remained unfused in very late prophase, each retaining its associated chromosome (fig. 14, 16). When the chromosomes have obtained their maximum contraction in late prophases, but have not yet migrated to the equatorial plate, the nucleoli may persist (fig. 15) with no appreciable change in size. The time and manner of complete disappearance of the nucleoli cannot be determined, but no trace of nucleolar material was ever found at metaphase.

The chromosome associated with the nucleolus cannot be identified until mid-prophase (fig. 9). During the later prophase stages, when the chromosomes are more contracted, the chromosome attached to the nucleolus is found to be of medium length, medianly constricted (fig. 14), and will hereafter be referred to as the "n-chromosome." There are a pair of such chromosomes in each sporophytic nucleus and a single one in each gametophytic nucleus (fig. 17).

The nature of the attachment of the n-chromosome to the nucleolus is variable. The end of the chromosome may be flush with the surface of the nucleolus (fig. 11, 13, 16, 19) or may be attenuated (fig. 9, 12). The connection may be severed and the nucleolus lie free (fig. 15). (The hetero-pyc-

notic chromosomes in figures 2, 15 and others will be discussed in a later paper.)

Concurrently with the enlargement of the nucleoli during telophase there is a change from faint pink to a red color in staining reaction with safranin. There is no corresponding loss in chromaticity nor in size in the prophases. An inconstant size difference between nucleoli exists in telophases (fig. 3-6); this is associated with a difference in stain intensity, the smaller nucleolus being less chromatic. All single nucleoli with one chromosome attached to each (fig. 3-5, 14, 16, 17) are spheroidal, as is a fusion nucleolus if the chromosomes are adjacent to each other (fig. 13). When two chromosomes are oppositely attached, the shape assumed by the nucleolus may be amoeboid (fig. 19) or spindle-shaped (fig. 9, 12).

Small buds appear on the nucleolus in prophases (fig. 18). These seem to be the "nucleolosomes" of Sorokin (1929). No connection between these and satellites could be found. The only indication that satellites may exist in this material was the occurrence of apparent satellites on two prophase chromosomes. Despite repeated searchings, these were found only once and cannot be considered significant. The chromosomes bearing these apparent satellites were in the same prophase from which figure 16 was drawn.

Many of the figures referred to do not show complete nuclei, since to draw all chromosomes would obscure the picture.

Discussion.—Although in *Pallavicinia* sporophytes the chromosomes from which the nucleoli arise cannot be identified in telophases, the constant association, during prophases, of the nucleoli with medianly contricted chromosomes of medium size indicates that it is these chromosomes which form the nucleoli in telophase. This conclusion agrees with the work of Heitz (1931), McClintock (1934), Dearing (1934), Kaufmann (1934), and others in assigning nucleolus formation to a particular element in a chromosome complement. There are, however, certain differences in details.

Heitz (1931), using Vicia species as material, found the nucleolar material associated with an achromatic constriction which set off a segment of the chromosome. A similar condition is described by Kaufmann (1934) in Drosophila melanogaster. In Zea Mays the nucleolus has been reported by McClintock (1934) to arise at an achromatic region and to be "organized in the telophase by an enlarged, morphologically distinct, deep staining chromosomal body, which appears at a definite position in one chromosome of the monoploid complement." In the nuclei of Ambystoma tigrinum each nucleolus arises from a pair of subterminal chromomeres in a particular chromosome (Dearing, 1934). However, in Pallavicinia the nucleolus in telophases is at the end of the n-chromosome. A similar telomitic attachment of chromosomes to the nucleolus is reported by Lorbeer (1934) in the liverwort *Frullania*.

The manner of origin of the nucleolus in Pallavicinia is at variance with that reported by Derman (1933) for Callisia, Paeonia, and Pinus, and by Zirkle (1931) for Pinus. These authors describe the formation, among the telophase chromosomes, of nucleolar globules which later fuse to form nucleoli. In Pallavicinia no indication of nucleolar material other than at the ends of chromosomes was found. The formation of nucleoli is not a random appearance of globules but occurs at a single point on a particular chromosome.

## SUMMARY

The nucleolus in Pallavicinia Lyellii arises in late telophase nuclei at the end of a particular chromosome designated the "n-chromosome." There is always a single nucleolus in each haploid nucleus. In each diploid nucleus there are two nucleoli or a single fusion nucleolus.

In late prophases the nucleoli may become detached from the nucleolus-forming chromosomes. During these stages there is no diminution in size nor chromaticity of the nucleoli. No nucleolar material can be identified in metaphases.

The n-chromosome is medianly constricted and is of medium length in respect to the other chromosomes of the haploid complement. The formation of the nucleolus at one point on a certain chromosome is an indication of the spatial organization of that chromosome.

# NEW SPECIES OF TAPHRINA AND NEW RECORDS FROM WESTERN NORTH AMERICA <sup>1</sup>

# A. J. Mix

IN THE summer of 1937, the writer was privileged to study collections of Taphrina in the herbarium of J. S. Boyce. Many of these collections are from the western United States or adjacent Canada. Also, during the past few years a number of specimens, all of them collected in California, have been received from Lee Bonar, H. N. Hansen, and H. Earl Thomas.<sup>2</sup> Altogether these collections contain a number of interesting new records and three undescribed species.

Taphrina Amelanchieri sp. nov.—Ascis hypophyllis, clavatis aut fere cylindratis, apice rotundatis, 20-30  $\mu$  longis  $\times$  8-13  $\mu$  crassis, cellula basilari fere cylindrata, 8-15  $\mu$  longa  $\times$  6-12  $\mu$  lata; ascosporis saepe octonis, ellipticis aut globosis, 3.5-

<sup>1</sup> Received for publication November 12, 1938.

<sup>2</sup> To these mycologists and to others mentioned in the text grateful acknowledgment is hereby made.

5.5  $\mu \times$  3–5  $\mu$ . "Scopas sagarum" gignens in ramulis Amelanchieri alnifoliae Nutt.

Asci hypophyllous, clavate to nearly cylindric, rounded at apex, 20–30  $\mu$  long  $\times$  8–13  $\mu$  wide; stalk-cells nearly cylindric, 8–15  $\mu$  long  $\times$  6–12  $\mu$  wide; ascospores usually eight in number, elliptic, 3.5–5.5  $\mu$   $\times$  3–5  $\mu$ . Causing witches' brooms on branches of Amelanchier alnifolia Nutt.

Near Frenchtown, Yreka, Siskiyou County, California, Klamath National Forest, E. P. Meinecke and J. S. Boyce.

Type material: Herbarium of J. S. Boyce (Yale University) No. 286.

This fungus is the first species of Taphrina known to occur on a member of the genus Amelanchier, although other species have been described on members of related genera: Crataegus, Pyrus and Sorbus.

In the witches' broom induced by Taphrina Amelanchieri (fig. 1), affected leaves bear the asci over the whole lower surface. Leaves are not noticeably thickened, and under the microscope leaf-cells show little alteration from the normal. Asci of the fungus are shown in figure 2E.

Taphrina Boycei sp. nov.—Ascis hypophyllis, apice rotundatis, in superiore parte fere cylindratis, basim dilatatis,  $30-60~\mu$  longis  $\times$  20-36  $\mu$  crassis, cellula basilari nulla sed asco quoque cum angusto pediculo mycelio conjuncto; ascis juvenilibus guttas pallido-flavas continentibus; ascosporis hyalinis, ellipticis aut globosis,  $4-5~\mu~\chi~3-5~\mu$ . Maculas flavas gignens in foliis Betulae fontinalis Sarg. et B. occidentalis Hook.

Asci hypophyllous, with rounded apex, in upper part approaching cylindric, broadened toward base,  $30-60~\mu$  long  $\times$  20-36  $\mu$  wide, attached to the mycelium by a slender pedicel; young asci containing pale yellow drops; ascospores hyaline, elliptic or globose,  $4-5~\mu~\times~3-5~\mu$ . Causing yellow spots (pale above) on leaves of (1) Betula fontinalis Sarg. and (2) B. occidentalis Hook.

Near Cheekye (1), and at Revelstoke, Big Bend Highway (2), British Columbia, J. S. Boyce and J. L. Mielke.

Type material: Herbarium of J. S. Boyce, No. 1938 (on B. fontinalis) and No. 1963 (on B. occidentalis). Additional material from Malcolm Wil-

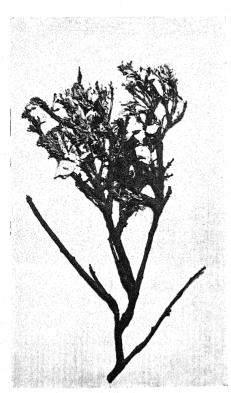

Fig. 1. Witches' broom on Amelanchier alnifolia caused by Taphrina Amelanchieri. (Photograph made from herbarium specimen. Shows some dermestid injury to leaves.) ×1/2.

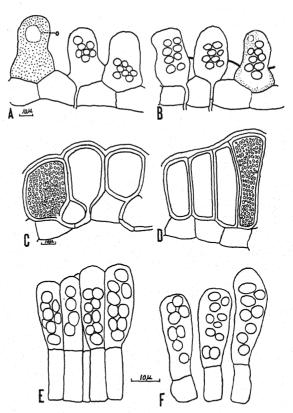

Fig. 2. A. Asci of Taphrina Boycei on Betula occidentalis (one ascus shows a yellowish globule, O, of oily material). B. Asci of the same fungus on B. fontinalis. C. Squarish asci of Taphrina flava, commonly found on the lower epidermis of the host. D. Subcylindric asci of T. flava, more common on the upper epidermis. E. Asci of Taphrina Amelanchieri. F. Asci of Taphrina flectans.

son (University of Edinburgh), New Westminster, British Columbia, July, 1938.

The fungus on Betula fontinalis has somewhat smaller asci than the one on B. occidentalis (fig. 2A, B):  $33-46 \,\mu \times 22-33 \,\mu$  as opposed to  $30-60 \,\mu \times 20-36 \,\mu$ . These slight size-differences might justify distinguishing the fungi on the two hosts as separate varieties, but do not seem sufficient to set them apart as different species.

Taphrina Boycei is obviously closely related to Taphrina flava Farl., which causes yellow spots on the leaves of Betula populifolia Marsh., and B. alba L. var. papyrifera (Marsh.) Spach, but the two fungi show several important differences. Taphrina flava has been studied from Seymour and Earle, Economic Fungi No. 171, and from two collections made by J. H. Faull and kindly loaned by him. Dr. Faull's collections are both on B. populifolia and were made at Kittery Point, Maine, July 7, 1929 (Herbarium of J. H. Faull, No. 9223), and at Chester, Lunenberg County, Nova Scotia, July 22, 1929 (Herb. J. H. F. No. 9252).

The spots caused by Taphrina flava are fairly definite on both surfaces of the leaf, while those

caused by T. Boycei are well defined on the lower surface but appear merely as paler areas in the leaf when viewed from above.

The asci of Taphrina flava are amphigenous. Roundish or squarish, nearly isodiametric asci (fig. 2C) like those figured by Patterson (1895) occur more abundantly on the lower surface of the leaf. On both surfaces, but preponderantly on the upper, occur elongate, nearly cylindric asci (fig. 2D). Asci of each type occur in a close-packed subcuticular layer; and since nearly all the asci mature at the same time, a considerable portion of the cuticle is lifted. The asci of T. Boycei may either be close packed or (by irregular ripening) scattered, and the cuticle may be lifted over a considerable area or may be perforated in places by single asci (fig. 2B). The ascospores of T. flava regularly proceed to budding within the ascus, filling it with minute conidia, before the overlying cuticle is lifted, while the asci of T. Boycei usually contain unbudded ascospores after the asci have burst through the cuticle. Characters common to the two fungi are the yellow color of host-lesions, the presence of globules of pale yellow, oily material in young asci, and the possession of a narrow pedicel connecting each ascus to the intercellular mycelium.

In the material studied the size-limits of the asci of  $Taphrina\ flava$  are greater than those given by Farlow (1883), Sadebeck (1890), and Patterson (1895):  $30-60\ \mu \times 15-30\ \mu$  as opposed to  $38-57\ \mu$ 

imes 20–23  $\mu$ .

Taphrina Pruni-subcordatae causing witches' brooms.—In May, 1938, a witches' broom on Prunus subcordata Benth. was received from H. Earl Thomas. Affected leaves are yellowed, not thickened, and bear asci of a species of Taphrina over the whole lower surface. The asci are clavate to cylindric, rounded or truncate at the apex, and provided with a stalk-cell. Dimensions are: asci, 27-43  $\mu \times 8$ -10  $\mu$ ; stalk-cells, 10-20  $\mu \times 8$ -10  $\mu$ ; spores, 4.5-6  $\mu \times 4$ -4.5  $\mu$ .

That this fungus may be biologically distinct from Taphrina Pruni-subcordatae (Zeller) Mix, which causes "fruit-pockets" on the same host is indicated by the following observations by Thomas. Diseased fruits were not searched for at the place of collection of the witches' brooms (near Elk Creek, California) but were found a few miles away. In another locality (Green Valley) fruits of Prunus subcordata were badly diseased, but no

witches' brooms were to be found.

Morphologically the fungus resembles Taphrina Pruni-subcordatae. Dimensions of the latter as given by Zeller (1927) are: asci, 54- $61~\mu$   $\times$  10- $13~\mu$ ; stalk-cells, 12- $16~\mu$   $\times$  5- $11~\mu$ ; spores, 6- $10~\mu$   $\times$  3.5- $5~\mu$ . In two collections of T. Pruni-subcordatae examined by the writer (Cordelia, California, April 22, 1936; and near Elk Creek, Glenn County, California, May 15-16, 1938; H. Earl Thomas), asci and spores are smaller and stalk- $^3$  Letter from H. Earl Thomas, May 17, 1938.

cells longer than reported by Zeller: asci 34-57  $\mu \times$  8-12  $\mu$ ; stalk-cells 15-30  $\mu \times$  6-10  $\mu$ ; spores 4-7  $\mu \times$  4-6  $\mu$ . It is possible that the variability would be even greater if more collections were examined.

On the basis of morphological similarity, and in spite of an apparent biological distinction, the witches'-broom fungus and the fruit-deforming fungus are considered to be the same: Taphrina Pruni-subcordatae.

In the Boyce herbarium there are specimens (No. 285) of leaf-curl on *Prunus subcordata*, collected near Taylorsville, Plumas County, California, April 23, 1915, by J. S. Boyce, accompanied by the note: "Common, causing witches' brooms. In some cases not deforming." The affected leaves, at least those selected for examination, show small leaf-curl lesions in which no mature asci are to be found. Whether this fungus is the same as the one described above cannot, therefore, be determined.

Taphrina flectans sp. nov.—Ascis hypophyllis, cylindratis aut clavatis, apice rotundatis aut truncatis, in magnitudine et in forma aliquanto variis,  $26-36~\mu$  longis  $\times$   $8-12~\mu$  crassis; cellula basilari  $8-18~\mu$  longa  $\times$   $7-12~\mu$  lata; ascosporis  $4.5-6~\mu$   $\times$   $4-4.5~\mu$ . "Scopas sagarum" gignens et ramulos flectans, in ramis Pruni~emarginatae Walp.

Asci hypophyllous, cylindric or clavate, at apex rounded or truncate, somewhat variable in size and shape,  $26-36 \mu \log \times 8-12 \mu$  broad; stalk-cell  $8-18 \mu \log \times 7-12 \mu$  broad; ascospores  $4.5-6 \mu \times 4-4.5 \mu$ . Causing witches' brooms and bending of twigs on *Prunus emarginata* Walp.

Near Donner Lake, California, July 13, 1938,

H. N. Hansen.

Type material in mycological herbarium, Univer-

sity of Kansas.

Specimens of this witches' broom were received from H. Earl Thomas soon after their collection by Hansen. Besides the usual "brooming" effect, formation of a number of crowded, slender twigs, a negatively geotropic curvature of twigs occurs. (A similar bending of the twigs of a witches' broom is described for *Taphrina Cerasi* (Fkl.) Sadeb. by Ráthay [1881].) Affected leaves are yellowed, unthickened, and bear asci over the whole lower surface.

In appearance and in variability, asci of this fungus (fig. 2F) resemble those of Taphrina Cerasi. Asci of T. Cerasi, according to several authors, are  $35-50~\mu~\times~5-12~\mu$ , stalk-cells  $6-16~\mu~\times~5-9~\mu$ , spores  $6-9~\mu~\times~5-7~\mu$ . Sadebeck (1893), however, states that the asci of this species are the most variable of "any yet studied," and it is the writer's experience that they are indeed variable in size. A number of specimens of T. Cerasi (all on Prunus avium L.) have been studied and the size limits found to be as follows: asci  $19-53~\mu~\times~7-15~\mu$  stalk-cells  $6-23~\mu~\times~4-8~\mu$ ; spores  $4-7~\mu~\times~3-6~\mu$ . It is common to find specimens in which the asci have a length of  $20-30~\mu$ . Since the size-limits of Taphrina flectans lie within those of T.

Cerasi, cross-inoculations involving these fungi and their respective hosts might prove interesting.

A specimen of leaf curl on P. emarginata was received from John Dearness. This was collected at Moscow, Idaho, June 9, 1935. The asci are amphigenous, variable in shape and size, are  $20-36~\mu~\times~8-12~\mu$ ; stalk cells  $8-16~\mu~\times~7-10~\mu$ ; spores  $4.5-6~\mu~\times~4-4.5~\mu$ . More knowledge of this fungus would be desirable, but it is tentatively referred to Taphrina~flectans.

Taphrina unilateralis on Prunus demissa.—Two collections of leaf-curl on Prunus demissa (Nutt.) Walp. have been studied: one from Gulers, Klickitat County, Washington, May 30, 1920, J. S. Boyce; the other from Berkeley, California, May 15, 1937, H. Earl Thomas. The asci are amphigenous, 23–40  $\mu \times$  8–13  $\mu$ ; stalk cells 7–16  $\mu \times$  6–10  $\mu$ ; spores 4–7  $\mu \times$  3.5–4.5  $\mu$ . This fungus was assigned by Atkinson (1894) to Exoascus varius Atk., causing leaf-curl of Prunus serotina Ehrh., "with some

doubt." Atkinson's Exoascus varius was assigned by Giesenhagen (1895) to Taphrina Farlowii Sadeb., deforming fruits of Prunus serotina, but no reasons were given for this reduction to synonymy. It is now apparent that Giesenhagen was right. Material of diseased P. serotina collected April 28, 1938, at Fayetteville, Arkansas, by J. C. Dunegan, and examined by the writer shows one fungus attacking leaves, twigs, and fruits. (When twigs are affected, they show malformations comparable to those caused on Prunus angustifolia Marsh. by Taphrina mirabilis (Atk.) Giesenhagen.) On leaves asci measure 15–30  $\mu$   $\times$  8–13  $\mu$ , stalk-cells 7-13  $\mu \times$  7-8  $\mu$ ; on fruits, asci 13-30  $\mu \times$  7-13  $\mu$ , stalk-cells 7-13  $\mu$   $\times$  7-10  $\mu$ . There is no doubt that the asci on fruits and leaves arise from the same mycelium.

If the leaf-curl fungus on Prunus demissa is to be assigned to a known species, it should be identified with Taphrina unilateralis (Peck) Mix. Measurements of this fungus given by Peck (1898) are stated in decimal fractions of inches. Converted by Saccardo they are: asci 40-52  $\mu$   $\times$  13-16  $\mu$ , stalk cells 13-16  $\mu$  imes 13-16  $\mu$ . These measurements are in error. Examination of Peck's type material (kindly loaned by H. D. House) shows actual dimensions to be: asci 23-33  $\mu$   $\times$  8-13  $\mu$ , stalk cells 8-18  $\mu \times 7$ -10  $\mu$ . The fungus on Prunus demissa is thus seen to be morphologically similar to the type of T. unilateralis, except for somewhat longer asci and narrower stalk cells. Another point of agreement between the two fungi is afforded by the amphigenous hymenium. Peck's "Type 1" of E. unilateralis has epiphyllous asci. His "Type 2," as well as other collections (Raleigh, North Carolina, May 11, 1936, R. F. Poole; Sandwich, Cape Cod, Massachusetts, June 6, 1937, D. H. Linder) examined show asci on both sides of the leaf. From these considerations the leaf-curl fungus on Prunus demissa is identified (for the present, at least) with Taphrina unilateralis.

Taphrina Robinsoniana.—Several specimens of catkin-deformations of Alnus spp. have been studied, as follows: on Alnus rhombifolia Nutt., Putah Creek, Lake County, California, September, 1931, H. E. Parks (communicated by Lee Bonar), asci  $33-53 \mu \times 15-18 \mu$ , stalk-cells  $10-17 \mu \times 10-17 \mu$ ; on A. rubra Bong., Deer Camp Ranger Station, Siskiyou County, California, August 26, 1913, J. S. Boyce, asci 26–40  $\mu \times 13$ –18  $\mu$ , stalk-cells 5–15  $\mu$  $\times$  10-17  $\mu$ ; on A. tenuifolia Nutt.. Glacier National Park, Montana, August, 1938, H. E. Bailev (communicated by Lee Bonar), asci 30-36  $\mu$   $\times$ 10-17  $\mu$ , stalk-cells 7-13  $\mu \times 8$ -13  $\mu$ ; on A. tenuifolia Nutt, Elk River, Clearwater County, Idaho, August, 1928, E. E. Hubert (Herbarium of J. S. Boyce No. 2073), asci 26-33  $\mu \times 10$ -13  $\mu$ , stalkcells 10-13  $\mu \times 10$ -13  $\mu$ .

These fungi may well be considered variants of  $Taphrina\ Robinsonia\ Giesenhag.$  That fungus, deforming catkins of  $Alnus\ incana\ Moench.$ , was described by Giesenhagen (1895) as having asci 29-37  $\mu \times$  6-10  $\mu$ ; stalk-cells 15-17  $\mu \times$  6-10  $\mu$ . Specimens of  $T.\ Robinsoniana\ on\ A.\ incana\ examined by the writer show no significant variations from these dimensions.$ 

Taphrina sp. indet. on Alnus.—Two collections of leaf-curl of Alnus rubra Bong. have been examined: the first made near Hebo, Tillamook County, Oregon, May 9, 1923, by J. S. Boyce; the second near Trinidad, Humboldt County, California, March 24, 1931, by H. E. Parks (communicated by Lee Bonar). Whole leaves are affected, thickened and much enlarged, and changed to a purplish color. The effect is like that produced on leaves of Alnus glutinosa Gaertn. by the European fungus, Taphrina Tosquinetii (Westend.) Tul.

Both surfaces of the leaf are covered with asci. These are irregularly cylindric, seated on the epidermis or slightly inserted, lack a stalk-cell, and measure  $46-76~\mu \times 15-23~\mu$ .

There are two leaf-curling species of Taphrina on Alnus whose asci lack stalk-cells: Taphrina japonica Kusano and T. Alni-japonicae Nishida, both on Alnus japonica Sieb. and Zucc. The former is described as having asci  $60-90~\mu \times 16-25~\mu$ , the latter  $60-80~\mu \times 16-26~\mu$ . Whether these species are really distinct and whether the fungus on Alnus rubra is identifiable with either cannot be told without further study.

Taphrina aurea on Salix laevigata and on Populus spp.—A new host-record is the occurrence of Taphrina aurea Fr. on Salix laevigata Bebb, collected at Mineral, Lassen County, California, September 10, 1911, by E. P. Meinecke (Herb. J. S. Boyce No. 282). The leaf-spots are deep yellow, as is usual for this fungus. The asci are amphigenous, contain numerous minute conidia, and globules of a pale yellow, oily substance. Asci are provided with a stalk-cell which may be short and pointed, but is often long and rhizoidal (even forking) and deeply inserted in the host. The dimensions are: asci  $66-102 \mu \times 20-27 \mu$ ; stalk-cells

20-89  $\mu \times 10$ -17  $\mu$ , narrowing to a point which may be no more than 3  $\mu$  wide.

Taphrina aurea, as it occurs on Populus nigra, usually has a short stalk cell or none. On other species of Populus it is rather variable, and on certain species, as on Populus Fremontii S. Wats., a long, rhizoidal, and occasionally forked stalk-cell may be present. Unless Taphrina aurea is to be split up into several species on different members of the genus Populus, the fungus on Salix laevigata must be placed in that species and not in a new one.

Taphrina aurea is also found on Populus Fremontii S. Wats. and on P. trichocarpa Torr. and Gray in several localities in the Pacific Coast states.

Taphrina spp. on ferns.—Recent records of species that have been previously collected in only one locality are: Taphrina californica Mix on Dryopteris arguta (Kaulf.) Wats., Big Sur River, Carmel, California, June 23, 1938, collected by C. E. Scott (communicated by H. Earl Thomas), the same fungus from San Francisquito Creek, Palo Alto, California, September 25, 1938, collected by R. H. Thompson, and Taphrina Faulliana Mix on Polystichum munitum (Kaulf.) Presl, Lake Cowichan, Vancouver Island, British Columbia, Malcolm Wilson.

### SUMMARY

Through the kindness of various mycologists, it is possible to report on species of *Taphrina* from western North America as follows:

A new species, Taphrina Amelanchieri, causes witches' brooms on Amelanchier alnofolia Nutt.

Another new species, *Taphrina Boycei*, causes leaf-spots on *Betula fontinalis* Sarg. and *B. occidentalis* Hook.

Taphrina Pruni-subcordatae (Zeller) Mix attacks shoots of Prunus subcordata Benth. It is possible that this fungus is biologically distinct from the form causing fruit-pockets on the same host.

A new species, Taphrina flectans, causes witches'

brooms on Prunus emarginata Walp.

The fungus causing leaf-curl of *Prunus demissa* (Nutt.) Walp., assigned by Atkinson to *Taphrina varia* is held to be *Taphrina unilateralis* (Peck) Mix. (*T. varia* is shown to be synonymous with *T. Farlowii* Sadeb.)

Fungi deforming catkins of Alnus rhombifolia Nutt., A. rubra Bong., and A. tenuifolia Nutt. are considered variants of Taphrina Robinsoniana

Giesenhag.

A leaf-curl of Alnus rubra Bong. is caused by an unidentified species of Taphrina showing resemblances to T. japonica Kusano and T. Alni-japonicae Nishida.

Taphrina aurea Fr., besides being well distributed on Populus Fremontii S. Wats., and on P. trichocarpa Torr. and Gray, occurs on a new host, Salix laevigata Bebb.

Fungi found in new localities are: Taphrina californica Mix on Dryopteris arguta (Kaulf.) Wats., and T. Faulliana Mix on Polystichum munitum (Kaulf.) Presl.

# THE CHROMOSOMES OF RANUNCULUS <sup>1</sup>

L. P. Coonen

THE FAMILY Ranunculaceae, with its 1200 species (Engler, 1936), has furnished much material for cytological study. Particular interest lies in the complex variation of chromosome numbers within the group, as shown especially by Langlet's (1927, 1932) examination of more than 200 species, with haploid numbers in an aneuploid series (including several euploid series) of 6, 7, 8, 9, 12, 14, 15, 16, 18, 20, 21, 24, 28, 29, 30, 32, 35, 42, 64, and 77.

On the basis of chromosome number and morphology, Langlet (1932) establishes two sub-families: Ranunculoideae, with long chromosomes, and Thalictroideae, with short and small chromosomes. These, in turn, are divided into tribes and subtribes, in some instances at great variance with Lotsy's (1911) classification. It is noteworthy that Langlet suggests assigning Glaucidium and Hydrastis (as well as Paeonia) to the Berberidaceae, because only in that family among the Ranales appears the haploid number 5.

Chromosome numbers have been reported for more than 100 species and varieties among the 250 species (Engler, 1936) of the genus Ranunculus. Souèges (1913) reported the haploid number in R. ficaria (=Ficaria ranunculoides Roth) as "about six." No extensive work was done until a decade later (Langlet, 1927, 1932; Larter, 1932; Sorokin, 1924, 1927a, 1927b, 1927c, 1927d, 1929; et al.).

R. acris, because of its small chromosome number, its floral dimorphism, and its dioecism, has been the most extensively studied species. Sorokin (1927a) found a triploid "gynodimorphic" form with a somatic number of 18. The progeny of a cross of triploid  $\times$  diploid (n = 18  $\times$  n = 12) included forms with somatic chromosome numbers of 12, 13, 15, 16, and 17. Apparently normal races with divergent numbers from different geographical locations were reported; 2n = 12 in Russia (Sorokin, 1924); 2n = 14 in the United States (Sorokin, 1927c, 1927d); 2n = 14 + varying numbers of fragments (usually 6) in Sweden (Langlet, 1927); a tetraploid with numbers ranging from 29 to 32 (2n = 28, the extra chromosomes resulting from early splitting) in Russia (Senjaninova, 1926); another tetraploid (2n = 28) in Germany (Langlet, 1932); and a sub-species (R. acris L. subsp. Boreauanus (Jord.) Rouy and Fouc.) with 2n = 16 in France (Hocquette, 1922). Evidence indicates that the typical diploid number for R. acris is 14, this number having been reported by nine investigators (table 1) studying plants from at least seven European countries, the United States, and Japan. Langlet (1927, 1932) found 14 in seven varieties (table 1). Whyte (1929) found the same number in six forms ("normal hermaphrodite," "female,"

<sup>1</sup> Received for publication September 29, 1938. The writer expresses his appreciation to Professor C. E. Allen, who suggested the subject of this research and offered many valued suggestions and criticisms during its progress and in the preparation of this paper.

"male," "abnormal," "minus normal," and "normal X abnormal").

Table 1. List of chromosome numbers in Ranunculus.

(This table follows the procedure of Gaiser (1930): Wherever the authority for a species name had been given by a writer it has been included. Though this may seem unnecessary in most cases, since the chromosome number given for a species name with or without the authority is usually the same, exceptional cases will be noted.)

MATERIALS AND METHODS.—Material of the following species was collected in or near Madison, Wisconsin: R. abortivus L. at Eagle Heights and Observatory Hill; R. acris L. Hort. at the Horticultural Gardens; R. fascicularis Muhl. at the University Arboretum; R. recurvatus Poir. at Poynette and Fern Dell; R. rhomboideus Goldie at Sauk City; R. sceleratus L. at Hope Lake; R. septentrionalis Poir. at Parfrey's Glen.

Identification of the specimens (excepting R. acris) was confirmed by Professor N. C. Fassett. In most instances some material was fixed immediately upon collection; the plants were then potted and kept growing in the greenhouse. Additional fixations were made from them later.

Seed of R. californicus Benth. was procured from Theodore Payne, Los Angeles, California; of R. monspessulanus Jord. and R. calandrinioides Oliv. from H. Correvon et fils, Geneva, Switzerland. After germination the seedlings were potted and grown to the flowering stage in the University greenhouse. Secondary roots were fixed for study.

Seeds of several other European species failed to germinate. Such factors as temperature, light, oxygen, moisture, and permeability of the achenes to water were artificially varied, with no success. Inasmuch as seeds of native species usually responded to ordinary germination methods, it is probable that most of the European ones were no longer viable. Even the percentage of germination in those two species which did produce plants was very low—in the better one only 3.5 per cent; the time required for germination was from 20 to 90 days.

Of the fixing reagents employed, the best general results for somatic divisions were obtained from Flemming's medium solution and from Karpechenko's and Belling's medifications of Navashin's

fixative. Carnoy's acetic acid-alcohol fixative followed by Heidenhain's iron-alum haematoxylin stain gave the best figures of meiotic chromosomes.

For somatic divisions, Smith's (1934) picric-acid modification of Newton's crystal violet-iodine stain was used almost exclusively. Haematoxylin stains the cytoplasm and its included granules, thus making difficult the recognition of satellites and setae. Smith's schedule, however, recommends that slides be left in xylol for at least 10 minutes after differentiation in clove oil; the writer's experience indicates that better results are obtained when this period is reduced to between 5 and 10 minutes. This change does not reduce the durability of the crystal violet stain; 18-months-old slides show no fading.

OBSERVATIONS.—The somatic chromosomes of the species of Ranunculus studied are in general characterized by subterminal, submedian, or median constrictions. Satellites were seen in every species except R. calandrinioides. Since the chromosomes are large, bent, and crowded, it is particularly difficult to find equatorial plates in which they are satisfactorily oriented. In the 28- and 32-chromosome species mitotic equatorial plates present at least 4 or 5 members, or portions of them, which are either perpendicular or oblique to the plate, or are completely or partially obscured by others. In these species specific morphological description of all the chromosomes is therefore difficult or impossible. Only such elements as are especially conspicuous because of their size, constrictions, and satellites can be recognized with certainty from one equatorial plate to another.

Sixteen-chromosome species offer less difficulty. Examination of mitotic equatorial plates often reveals distinct morphological characteristics.

R. abortivus L. 2n = 16.—This number is the same as that reported for the species by Sorokin (1929) in Minnesota, Langlet (1927) in Sweden, and Larter (1932) in England. Sorokin represents the complement by the formula 2 (3V + v + 3J + 1'). Equatorial-plate figures (fig. 4) in the writer's material are in general accord as to chromosome size and form with Sorokin's figures 1 and 2. A pair of chromosomes bearing satellites is conspicuous. Other authors have given only numbers, neither figuring nor describing the chromosomes in this species.

R. rhomboideus Goldie. n = 8, 2n = 16.—The chromosomes (fig. 17, 18) of six equatorial plates, from root tips of three plants, show the characteristics and average lengths indicated in table 2. One chromosome pair (c) is satellited.

The average chromosome diameter is about 0.75  $\mu$ . This is neither stable nor consistent, because of early and varied degrees of spatial separation in equatorial-plate chromosomes. Chromosome length, too, varies somewhat with the stages of mitosis. Pierce (1936) has pointed out that in *Viola* chromosome size and volume vary from cell to cell and (1937) that about a 300 per cent increase in chromosome volume occurs when "excess phosphorus" is

<sup>\*</sup> Anaphase views indicate that these are telomitic.

used in the soil medium as compared with "minus phosphorus." Evidently variations of similar order may occur in nature.

Variations in size of satellites and in length and diameter of setae have been noted in mitotic equatorial plates, as shown in figures 17, 18, 25, 26, and 27. Tandem satellites (fig. 25) were seen in two instances. An early separation of the halves of the split satellite doubtless explains the appearance of two parallel members on one chromosome (fig. 26).

 $R.\ acris$  L. Hort. 2n=14.—Extensive cytological work has previously been done on this species (table 1). The author's preparations were made from a few buds from a vigorous double-flowered horticultural variety. The cells of young petals showed the diploid number (2n=14). The material was unfavorable for the study of chromosome morphology.

R. calandrinioides Oliv. 2n = ca. 18.—The paucity of available material for study of this species makes cytological determinations uncertain. The only two plants which grew from seed developed very slowly under greenhouse conditions and showed few mitoses in the root tips. Madison's elevation of approximately 900 feet offers conditions vastly different from the plant's native elevation of 8,000 to 10,000 feet (according to Hooker's (1889) citation of Oliver's original description).

When chromosomes are separate they are well defined; constrictions are definite, but the identity of some members of the plate shown in the upper right of figure 33 is questionable. The average diameter (ca.  $1.0 \mu$ ) is greater than in the other species studied, and lengths are considerably less, varying from 1.75 to  $4.75 \mu$ . Fixation was in Belling's modification of Navashin's fixative.

The leaves are strikingly different from those commonly found in the genus, being linear, entire, glabrous, gray-green, and parallel-veined. These divergences, together with the apparent chromosome number (ca. 18) and differences in chromosome size may justify the separation of this species from the genus.

R. sceleratus L. 2n = 32.—Since eight is the commonest basic chromosome number for the genus (table 3), the 16 chromosome pairs present in diakinesis (fig. 16) indicate the possibility of allotetraploidy in this species.

The somatic complement is unique in possessing a pair of large-satellited chromosomes (fig. 13). The satellite diameter  $(0.50 \,\mu$  to  $0.75 \,\mu$ ) is the largest yet figured in the genus. Because of their size the satellites afford a clear contrast to the smaller irregular inclusions of the nucleoplasm and cytoplasm; thus their behavior in mitosis is relatively easily observed. After fixation in Belling's modification of Navashin's fixative and staining in Smith's (1934) crystal violet-iodine, the criteria for favorably stained material are the deep violet of the chromosomes and satellites and the yellow translucency of the nucleoli.

Bodies which may reasonably be assumed to be satellites are very frequently seen lying adjacent to or contiguous with the nucleolus in metabolic cells (fig. 7). Sometimes they are a short distance away from the nucleolus, possibly in consequence of fixation. As many as ten such associations (in as many nuclei) are visible in a single microscopic field. Commonly the bodies in question are recognizable in connection with the nucleoli of a group of three (fig. 15) or four contiguous cells.

In the earliest prophases (fig. 8), when chromonematal clumps are resolving in the nucleoplasm, a clear "Hof" apparently isolates the nucleolus and satellites from other chromophilic substances. A little later (fig. 10) chromonematal strands can be

seen directed toward the satellites, apparently touching them; visible setal attachment is sometimes certain (fig. 9). When the chromonemata and matrices contract to deeply staining chromosomes in the median and late prophases (fig. 11,

12), the definite setal attachment is more often observed. In these stages the satellite, seta, and proximal end of the chromosome usually lie on the surface of the nucleolus.

At the metaphases the halves of the split satellite,

associated seta, and chromosome separate—those of the satellite and seta sometimes precociously. Excessive destaining at this stage renders the chromosome delicately purple and translucent, while the satellite remains a deep violet.

In the telophases the satellites persist after the apparent dispersion of the organized chromosomes and can be seen on the surfaces of the incipient nucleoli (fig. 14).

During the entire mitotic cycle the satellites undergo no appreciable change in morphology nor in their affinity for the crystal violet stain.

R. Monspessulanus Jord. 2n = 32.—This European species, also a tetraploid, grew slowly under greenhouse conditions, and its root tips showed relatively few mitoses. Equatorial plates ordinarily showed 32 somatic chromosomes, two bearing single satellites; in one instance an equatorial-plate chromosome bore tandem satellites (fig. 2). One root tip showed two fragments (fig. 2). Since some equatorial plates definitely showed the fragments lying about midway between the surfaces of the  $10 \mu$  section, they could not be attributed to sectioning.

R. californicus Benth. 2n = 28.—This tetraploid possesses a pair of chromosomes with satellites of unequal size (fig. 3). Nucleoli of resting nuclei (fig. 32) show two attached bodies, likewise of unequal size.

R. fascicularis Muhl. 2n = 32.—Two small satellites are found in this tetraploid species (fig. 28, 30). Variations in size of satellites and in length of setae have been noted. Tandem satellites were found in a single instance (fig. 29).

R. recurvatus Poir. 2n = 32.—Two satellites have been seen in many cases. In each instance the chromosomes were too crowded to distinguish all members of the equatorial plate. Figure 5 shows the tetraploid number, with but one satellite; its setal connection could not be determined.

R. septentrionalis Poir. 2n = 32.—Varying numbers of satellites have been seen in this tetraploid species; the maximum, 5, are shown in figure 6. Because of the large chromosome number and of the size and orientation of the chromosomes it has been impossible to determine whether or not this is a constant number. One equatorial plate showed tandem satellites on one chromosome.

Discussion.—Chromosome numbers of 95 forms of 85 species of Ranunculus thus far studied, including those reported in the present work, are summarized in table 3 and figure 34. In case an author has expressed uncertainty or has studied inconstant aberrant forms, his report has been omitted.

The basic chromosome number 6 has been reported but once in R. acris (table 1). A race, 2n=24, of R. Ficaria is assumed to be a triploid with the basic number 8, rather than a tetraploid with the basic number 6. The diploid numbers 16 and 32, and no other multiples of 6, have been reported in the species.

As 8 is the most frequent basic chromosome num-

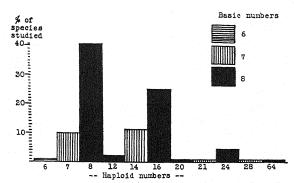

Fig. 34. Graph showing distribution of haploid and basic chromosome numbers in Ranunculus thus far studied.

ber (table 3), others (6 and 7) are possibly derived from it. Sorokin (1927b) compared the chromosome complement of a 14-chromosome race of R. acris with that of a 12-chromosome race and found the latter to differ from the former in the absence of a pair of large chromosomes (9.4  $\mu$  in length). All pairs of chromosomes in the 14-chromosome race differ from one another; it is not likely that through trisome- or tetrasome-formation it had been recently derived from the 12-chromosome race. Chromosome loss may conceivably have been the cause of derivation of the basic number 7 from 8. However, there is no evidence to support this possibility; gene mutations and structural differentiation in the course of evolution may have altered individual chromosome character so greatly that morphological comparison is not a valid criterion.

Both allopolyploids and autopolyploids probably exist in the genus. Determinations of either type in the few species attempted are uncertain; no significant cytogenetic work has been done.

Fragments have been reported in several species of the genus. Jane (1932) found a pair of frag-

ments in "some metaphases" of R. parviflorus. Larter (1932) reported an extra pair of small chromosomes in one plant of R. Ficaria. Langlet (1927) saw varying numbers of "e-Chromosomen" (usually 6) in a root tip of R. acris growing wild in Sweden; he attributed their origin to complete constriction (Einschnürung) in the positions of subterminal constrictions in normal chromosomes. The origin and significance of the fragments in R. monspessulanus (fig. 2) are quite uncertain.

A few tetraploid cells (with about 64 chromosomes) have been found by the writer in root tips of R. monspessulanus and R. fascicularis. A similar occurrence is reported by Larter (1932) in R. sardous and R. Ficaria. He found tetraploid strains in the latter species and suggested that they may have originated from such cells of a diploid

strain.

Since Navashin (1912) reported the satellites of prophase and metaphase chromosomes of Galtonia candicans, and similar bodies attached to the nucleoli of resting cells, various similar associations have been reported in other organisms. Heitz (1931) postulated the ubiquity of satellites. Kuhn (1928) has listed 130 species, representing 38 genera, known to possess satellite chromosomes. Work since then has shown satellites to be even more prevalent. Babcock and Cameron (1934) reported them in 108 Crepis species; Resende (1937) found them in 185 species (the majority members of the section Aloinae of the Liliaceae); they have been reported in almost every genus of the Ranunculaceae.

As early as 1911 Stevens (1911) figured a pair of satellite chromosomes, which she called "heterochromosomes," in the mosquito. Since 1933 satellites have been reported in five other animals: Drosophila, Bibio, Amblystoma, Opalina (cited by Resende (1937), p. 759), and Salmo (Prokofieva, 1934).

In the present work no setal connection was determined between nucleolus and satellite in resting somatic nuclei, as figured by Sorokin (1924, 1929) and Hasse-Bessell (1928). Contiguity of nucleolus and satellite was noted in R. rhomboideus (fig. 20-23), R. californicus (fig. 32), and R. sceleratus

(fig. 7-12, 14).

Among the various reported opinions as to the function and nature of satellites are the following: Navashin (1927) considered that a satellite is picked up by the chromosome during the prophases and that, as a terminal chromomere, it plays some rôle in the attachment of the spindle fiber to the chromosome. De Mol (1927) considered a similar structure to be a nucleolar globule not taken up by the chromosome. Delaunay (1915) considered satellites to be concerned with chromosome contraction. Darlington (1937) held a satellite to be a short chromosome arm unique only in its formation by a broad constriction; Heitz (1931) thought satellites concerned with nucleolus-formation. But McClintock (1934) finds the nucleolus formed in connec-

tion not with a satellite but with a special chromatic portion of the chromosome near the seta.

The writer's observations of the satellite of R. sceleratus and its behavior in mitosis suggest the following: (1) that it is present in all mitotic stages, having been seen in all but early telophase, at which time conditions are most unfavorable for its observation; (2) that it has an affinity for the nucleolus, satellite and nucleolus having been seen in apparent contact whenever both bodies are present; (3) that its chromophilic qualities are different from those of both nucleolus and chromosome body; in destaining it retains a deep crystal violet stain after equatorial-plate chromosomes have been almost, and the nucleoli entirely, destained; (4) that it is apparently morphologically constant; (5) that it is always associated with the chromosome, whether the chromosome is or is not recognizable as a stainable entity; soon after the nuclear material appears as small irregular stainable clumps of chromatin in the early prophases the satellite has been seen attached to ill-defined chromonematal strands (fig. 9, 10).

Variation in size of satellites or in length of setae has been noted in certain of the species here studied (fig. 2, 18, 27, 28, 30); but since such delicate structures and their observation may be influenced by any one, or by any combination, of several variable factors (mitotic stage of chromosome, reaction to fixative, reaction to stain, and orientation of the observed chromosome), no explanation is attempted.

Tandem satellites have been observed in rare instances (fig. 2, 25, 29, 31). Taylor (1926) has found similar tandem satellites in the root tips of a single Allium plant, the homologous chromosome in this case probably lacking a satellite. Meurman (1929) figures four chromosomes of Aucuba japonica with tandem satellites, definitely separated by threads. He evidently considers them to be small constricted portions, for he does not refer to them as satellites.

The origin of tandem satellites in R. fascicularis and R. septentrionalis, the homologue apparently bearing none, may be attributed to faulty disjunction in the metaphases. But in case the homologue does bear a single satellite (fig. 2, 25), the origin of the double structure would necessarily be referred to an ancestral plant, some of whose gametes contained tandem satellites and others none. A gamete of the former would have fused with a gamete having a single-satellite chromosome to produce the condition here found.

## SUMMARY

Chromosome numbers were determined as follows: Ranunculus abortivus L., 2n = 16; R. rhomboideus Goldie., n = 8, 2n = 16; R. acris L. Hort., 2n = 14; R. calandrinioides Oliv., 2n = ca. 18; R. sceleratus L., 2n = 32; R. monspessulanus Jord., 2n = 32; R. californicus Benth., 2n = 28; R. fascicularis Muhl., 2n = 32; R. recurvatus Poir., 2n = 32; R. septentrionalis Poir., 2n = 32.

The average lengths of the respective somatic chromosomes of R. rhomboideus are: 2.25  $\mu$ ; 3.0  $\mu$ ;  $3.5 \mu$ ;  $4.0 \mu$ ;  $4.75 \mu$ ;  $5.25 \mu$ ;  $5.5 \mu$ ;  $6.5 \mu$ .

Divergences in chromosome morphology and number, as well as in vegetative characteristics, may justify the removal of R. calandrinioides from the

Satellites were observed in all species studied excepting R. calandrinioides.

Two large satellites were seen at all mitotic stages, except early telophases, in R. sceleratus. Their chromophilic qualities are different from those of both nucleolus and chromosome body. They are apparently in contact with the nucleolus whenever it is present, and are always associated with their respective chromosomes.

Tandem satellites were found in isolated cases in R. monspessulanus, R. rhomboideus, R. fascicularis, and R. septentrionalis. Variations in satellites and setae were noted in some species; these may be due to variable factors in the preparation and observation of material.

A few tetraploid cells were observed in root tips of R. monspessulanus and R. fascicularis.

A pair of fragments was found in the equatorial plates in one root of R. monspessulanus.

Of the 95 forms of 85 species thus far studied in the genus, 74.71 per cent have the basic number 8; 24.14 per cent, 7; and 1.15 per cent, 6. Basic numbers 6 and 7 are probably derived from 8.

# POTENTIALLY UNLIMITED GROWTH OF EXCISED PLANT CALLUS IN AN ARTIFICIAL NUTRIENT <sup>1</sup>

Philip R. White

ONE of the ultimate objects of the cultivation of isolated plant or animal organs or tissues has always been, as Haberlandt (1902) long ago pointed out, the investigation of problems concerning the metabolism of the individual cell and its relation to neighboring cells. This object can be fully attained only if the cell can be isolated from its fellows, either anatomically or physiologically. Haberlandt and his immediate pupils sought to isolate cells anatomically. But the same end can be attained approximately if a completely undifferentiated mass of tissue can be grown in which all cells are alike and hence exert like influences on one another. It is for this reason that an "undifferentiated" state has come to be considered one of the irreducible characteristics of a "tissue culture." There is, however, another irreducible characteristic of a true "tissue culture" which must be demonstrated if the metabolism of the cells is to be considered normal. That is unlimited capacity for growth. This question has been repeatedly discussed elsewhere (White, 1931, 1936).

As was pointed out in earlier papers (White, 1934, 1936), the root cultures maintained in this laboratory for the past six years satisfy the second requirement, of unlimited capacity for growth, but are by no means undifferentiated. Gautheret's cultures of excised cambium (1934, 1935, 1938a, 1938b), Nobécourt's carrot root cultures (1937, 1938), and Bonner's pea-pod cultures (1936), on the other hand, are relatively undifferentiated and have the appearance of tissue cultures. Gautheret has grown cambium cultures for more than a year, through five or six passages, thus furnishing evidence of a possible capacity for unlimited growth. It seems probable that he has, therefore, fulfilled both these requirements and is to be credited with the first true plant tissue cultures. His observations, however, do leave some doubt on this score. The tissue fragments used in his cultures were relatively large, one to two centimeters in diameter, and contained considerable stored material. The growth rates reported were so low that transfers could be made only once every 4 to 6 weeks. The cultures may have survived at the expense of the stored nutrients within the explant and may not be capable of unlimited growth. Nobécourt's cultures likewise grew slowly and were of relatively brief duration. Bonner's results were still less satisfactory. A more adequate demonstration is needed than that furnished by the data of these authors.

I have for some time been interested in a hybrid tobacco resulting from the cross Nicotiana glauca  $\mathcal{P}$   $\times$  N. langsdorffii  $\mathcal{S}$  (Kostoff, 1930; Levine, 1937). This hybrid has an unusual capacity for prolifera-

tion, producing calluses and galls at any point on stem or leaf which has been mechanically abraded. Callus tissue may also develop in the absence of obvious wounding. It seemed possible that tissues of such a plant might be especially favorable for cultivation in vitro. This paper reports the results of an investigation of this possibility.

The nutrient used was the same as that employed for cultures of isolated roots, consisting of a modified Uspenski solution, 2 per cent sucrose and 0.01 per cent of an extract of dried brewer's yeast (White, 1934). It early became evident that most callus tissues would not float on the surface of the nutrient as do roots, so that their oxygen supply

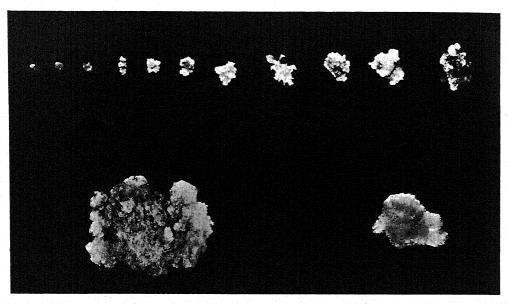

Fig. 2-4.—Fig. 2 (above). A series of cultures of excised hybrid tobacco callus cultivated in vitro. The cultures vary in age from 0 (extreme left) to 10 weeks (extreme right). ×1.7.—Fig. 3 (lower right). Detail of a tissue fragment similar to that shown at the left in figure 2. The surface is irregular, but there is no evidence of differentiation. ×20.—Fig. 4 (lower left). Detail of a 20-weeks-old culture. There is still no macroscopic evidence of differentiation. The tissue mass is so friable as to be easily broken up with a needle. ×2.3. (Photographs by J. A. Carlile.)

might be expected to be inadequate in a liquid nutrient (Zimmerman, 1930; Gautheret, 1935; see also various papers by W. A. Cannon and by D. R. Hoagland and associates). To obviate this difficulty, 0.5 per cent of thoroughly washed agar was added to the above nutrient to make a semi-solid medium. Young stems of the plants were stripped of their leaves. In the laboratory they were broken 4 to 5 cm. back of the tips, where the tissues were brittle enough to break without tearing. Clean. aseptic surfaces were thus exposed. With a sterile scalpel, cones of tissue were removed from the exposed surfaces, the tissue masses consisting of medulla and procambial strands. The excised masses were always less than 5 mm. in greatest diameter. They were placed on nutrient agar in either 125 ml. Erlenmeyer flasks or 40 ml. Pyrex test tubes and set aside in diffuse daylight.

Where such fragments contained only medullary parenchyma, no growth occurred, and the tissues soon turned brown. Wherever procambial strands were present, however, proliferation from these regions began almost immediately. Irregular protuberant masses of callus were formed, which early took on a bright green color. After from one to two weeks, these masses were cut away from the original explant and transferred to fresh nutrient. The cultures were divided and transferred to fresh nutrient at biweekly intervals through 10 passages. Five rapidly growing cultures were then selected for more detailed study and the remainder dis-

<sup>2</sup> This color was retained in cultures that were subcultured at frequent intervals but disappeared in older cultures, without causing any concomitant reduction in growth rate. carded. These 5 were divided into 25 fragments, each less than 2 mm. in diameter. thenceforth were at weekly intervals, and each culture was regularly divided into as many pieces of 1 mm. or less diameter as possible, 25 cultures being retained in each passage for the next 10 passages. From figure 1 it is clear that by the 15th passage all 25 cultures were derived from culture No. 1 of passage 11 and culture No. 2 of passage 12. The tissue fragment used as No. 2, passage 12, had therefore increased 25-fold in 3 passages. The detailed record shows that each fragment had increased on an average about 3-fold per passage of 7 days, or about 50 per cent per culture per dayan increment rate which compares favorably with that observed in isolated roots. At the end of the 20th passage, the number of cultures was reduced to 10 to conserve space. These cultures had been maintained through 40 passages on November 3, 1938, and are still in excellent condition at the time of writing this paper.

An increase of 3-fold per passage for 40 passages would represent an increase of  $3^{40} = \text{ca. } 1.2 \times 10^{19}$ , or a dilution of any material contained in the original explant to a mass of the order of  $10^{-19}$  times its original mass in each culture. It is not to be supposed that any material could be a growth-limiting factor at such a dilution. These cultures, therefore, appear to satisfy the second requisite of a tissue culture, unlimited capacity for growth.

Figure 2 shows a series of cultures prepared by setting aside one culture each week for the ten weeks involved in passages 11 to 20. The oldest piece (extreme right) had thus been undivided for

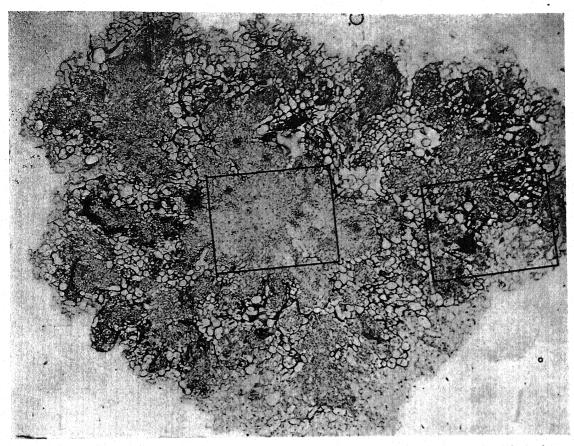

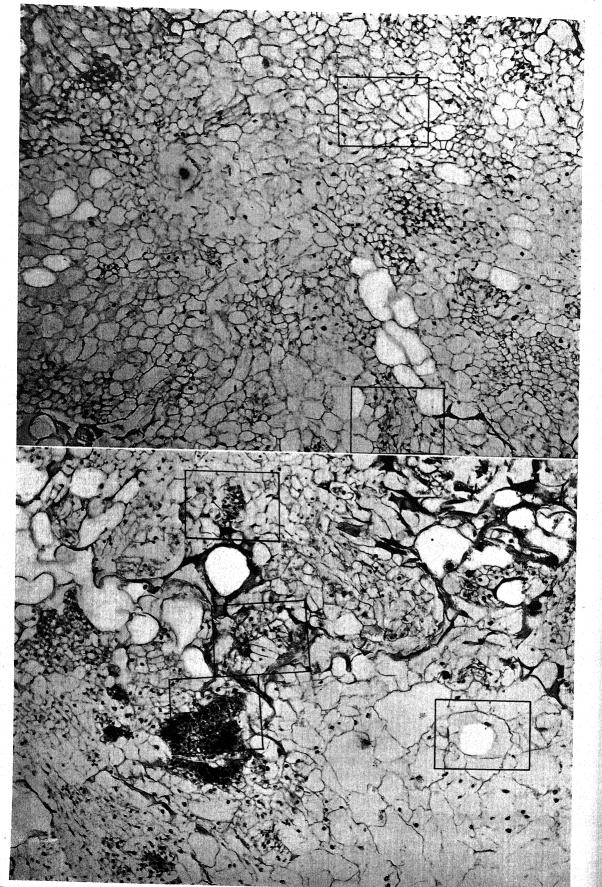

Fig. 5. Transverse section through an 8-weeks-old culture similar to that shown third from the right in figure 2. The central area (see fig. 6) is relatively uniform, while the marginal area (see fig. 7) is less compact and is made up of irregular masses of tissue which might be mistaken for organized growing points or leaves. ×30. (Photograph by J. A. Carlile.)

10 weeks, while the youngest (extreme left) was photographed at the time of subculturing and shows the size of piece used in starting each subculture. Figure 3 shows the detailed appearance of such a culture at the beginning, and figure 4 a similar culture after 20 weeks' growth. There is little if any macroscopic evidence of differentiation. The microscopic structure is in keeping with this appearance. Figures 5 to 13 were all taken from a single transverse section through the center of a culture which had been maintained for 8 weeks without being divided. In general appearance the section shows a central core of tissue resembling medulla (fig. 5, 6) surrounded by an irregular corona of less compact masses (fig. 5, 7). central core is made up of relatively uniform, moderately large cells with scattered areas of what may have been meristematic tissue and occasional groups of scalariform cells suggesting differentiation into xylem (fig. 6, 8, 9). These xylem elements are isolated and obviously incapable of normal function, since they do not extend for any considerable distances through the mass. The younger, peripheral regions show a much wider variation in cell type. The meristematic areas are more frequent

(fig. 7, 10, 11) and are obviously functional. Growth thus occurred by means of "growing points" rather than cambium, but these growing regions are not identifiable as "stem" or "root." Growth was random, neither polarized nor resulting in oriented differentiation. The meristematic cells evidently divide for a time, then enlarge (fig. 7, 11, 13), form irregular bands of "giant cells" (fig. 7, 12), and these finally either become thickened (suberized?) (fig. 5, 7) or else are crushed by the new growth. The outermost portions of the tissue mass are usually made up of large, thin-walled cells (fig. 7, 12). The cells throughout the culture contain considerable quantities of starch, although they are nearly if not completely devoid of chlorophyll (fig. 9, 10, 11, 12, 13). Nowhere were the loose "pleurococcoid" growths figured by Gautheret (1934, 1935, 1938b) nor the arcuate cells of Nobécourt observed (Nobécourt, 1937-compare with the sloughed cortical cells of wheat-root cultures. White, 1932, and those observer by Scheitterer, 1931).

These cultures, then, show a behavior similar to that of attached callus but do not undergo anything like the same degree of differentiation (Le-

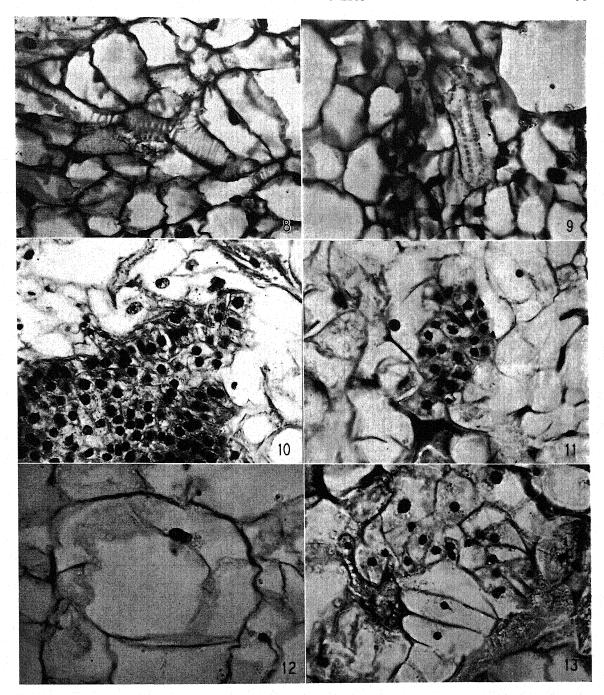

Fig. 8-13.—Fig. 8. Detail of a band of scalariform cells from the upper part of figure 6.  $\times 435$ .—Fig. 9. Detail of scalariform cells from the lower part of figure 6.  $\times 435$ .—Fig. 10. Large meristematic area from the center of figure 7.  $\times 435$ .—Fig. 11. Small meristematic area from the upper part of figure 7. Compare the size of these cells with those in figures 12 and 13.  $\times 435$ .—Fig. 12. Detail of a "giant cell" from the right hand part of figure 7. Compare in size with the meristematic cells of figures 10 and 11.  $\times 435$ .—Fig. 13. Fig. 6 (above). Detail of the central part of figure 5. The cells of this region are of relatively uniform size, thin-walled, parenchymatous in nature except for scattered denser groups of semi-meristematic cells and occasional scalariform cells (see fig. 8 and 9). ×138.

Fig. 7 (below). Detail of a marginal area from figure 5. There are scattered clumps of meristematic cells (see fig. 10, 11) with bands of necrotic tissue, areas of parenchymatous "giant cells," and areas of intermediate type. What at low magnification (fig. 5) appeared to be organized stem growing points appear at higher magnification to be quite unorganized. ×138. (Photographs by J. A. Carlile.)

vine, 1937). It is not possible to identify phloem, cambium, pheloderm, sclerenchyma, nor any other normal cell type except parenchyma, meristem, and an occasional isolated scalariform cell. The cultures, while not quite unorganized, are at least quite disorganized. The tissues are not pith, wood, bark, nor even typical callus. These are not organ cultures. While not strictly comparable to the "pure line" cultures of the animal tissue culturists, they do represent a very close approach thereto. Although all the cells are not quite alike, these masses represent cultures of cells characterized by a very simple and primitive type of growth. It is believed that we have here at last a very near approach to a true plant tissue culture, which should provide us with a new means of approach to the problems of the physiology of the spermatophyte cell.3

<sup>3</sup> Since preparing this paper for publication, similar cultures have been successfully established from Nicotiana tabacum L., Lycopersicon esculentum Mill., and Beta vulgaris L., and are now (January 11, 1939) in the sixth passage. This capacity is, therefore, not a special characteristic of the N. glanca × N. langsdorffii hybrid, but a more general characteristic of normal plants.

## SUMMARY

Excised callus obtained from proliferating procambial tissue of a hybrid Nicotiana (N. glauca X N. langsdorffii) has been maintained in culture in an environmental complex and nutrient similar to those earlier developed for cultivation of excised roots, through 40 passages of one week duration Cultures regularly increased about 3-fold in volume each week, giving a total theoretical increment of  $3^{40} = ca$ .  $10^{19}$ . The conditions can, therefore, be considered adequate for unlimited growth of this material. These cultures show no evidence of differentiation or polarity except for an occasional scalariform cell. Being undifferentiated yet capable of unlimited growth, they appear to satisfy the two main requirements for a true "tissue culture."

## ARTIFICIAL INDUCTION OF POLYPLOIDY IN ALFALFA 1

D. C. Cooper

RANDOLPH (1932) devised a method for the artificial induction of polyploidy in maize wherein he subjected the ear shoot to temperatures of 30° to 45°C. for half-hour intervals at the time of the first division of the zygote. Since then Atwood (1936) and Muntzing, et al. (1936) have made

<sup>1</sup> Received for publication December 2, 1938.

Papers from the Department of Botany and the Department of Genetics (No. 237), Agricultural Experiment Station, University of Wisconsin. Published with the approval of the director of the station.

use of a similar technique and induced polyploidy in sweet clover and barley, respectively. Dorsey (1936) obtained tetraploid plants of wheat and rye by subjecting the entire mother plant to a temperature of approximately 43°C. for 20–30 minutes at the time of division of the zygote. Peto (1936) kept barley seedlings at a temperature of 35°C. for a period of seven days following germination, after which time they were carried to maturity under normal growth conditions. One plant produced a spike bearing both diploid and tetraploid florets.

One contains two nuclei. Magnification: A-J,  $\times 2560$ ; K,  $\times 1100$ .

During the spring of 1936 an attempt was made to induce polyploidy in alfalfa (Medicago sativa L.) in a similar manner. Fertilization takes place in this plant between 24 and 28 hours after the tripping of the flower, and the division of the zygote nucleus occurs three to four hours thereafter. The apical cell of the resulting pro-embryo continues to divide so that ultimately the pro-embryo consists

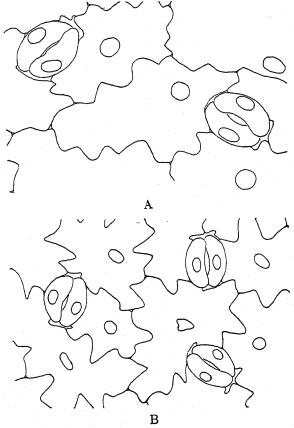

Fig. 2. Stomata of the lower epidermis from mature leaves of tetraploid (A) and diploid (B) alfalfa. ×413.

of an axial row of six cells (Cooper, 1935). Proembryos at this stage are usually present 72 hours after pollination.

The flowers of a number of racemes were tripped, and the heat treatment was applied for a period of one hour at intervals ranging from 36 to 50 hours after tripping. Each inflorescence was treated once, the treatment being at a given constant temperature within the range 41° to 46°C. The apparatus used was designed by Barlow and Brink and has been described in detail by the latter (1936). The same device was used by Atwood (1936) in the production of tetraploid and aneuploid forms of Melilotus alba.

The 400 seeds obtained from the treated racemes were grown in the greenhouse, and the somatic number of chromosomes of each resulting plant was determined by means of aceto-carmine smears. One

plant proved to be tetraploid (fig. 1A, 2n = 64); all the others were diploid (fig. 1B, 2n = 32). The seed from which the tetraploid was obtained came from a raceme which had been subjected to a temperature of  $42^{\circ}$ C. during the interval between 47 and 48 hours after pollination. The writer is not aware of any other case of tetraploidy in alfalfa, either natural or induced, and therefore assumes that the 4n plant obtained can be ascribed to the heat treatment.

Many tetraploids are characterized by giant types of vegetative organs. Such giantism did not occur in the alfalfa tetraploid. There were, however, measurable increases in size. The stems, leaves, and the individual flowers of each raceme were somewhat larger than those of the diploid plants, the greater size of the flowers being most noticeable. A high percentage of the pollen grains from the 4n individual were abortive. The average diameter of the plump pollen grains was distinctly greater, the computed volume of such grains being approximately twice that of grains from 2n plants. The mature leaves of the tetraploid have larger and more widely spaced stomata than do those of the diploid (fig. 2A, B). The stomata of the former average 29.6  $\mu$  in length and 22.2  $\mu$  in width as compared with an average length and width of 22.8  $\mu$  and 16.4  $\mu$ , respectively, in the latter. The epidermal cells are likewise larger in the tetraploid individual. Similar size relations of pollen grains, stomata, and epidermal cells have been reported in artificially induced tetraploid maize (Randolph, 1935).

No viable seeds were obtained from the tetraploid plant. Material for the study of meiosis was collected, and a number of cuttings was made before the plant was transferred to the field. Fifteen of the plants obtained from cuttings were brought into bloom in the greenhouse during April and May, 1938. The flowers were regularly tripped in the hope of obtaining seeds. Twelve pods were formed from which an equal number of more or less shriveled seeds were harvested. Three of these seeds germinated, and the young plants are growing well. The stomata in each of these offspring are comparable in size to those of the parent plant, and the somatic chromosome number in each case is 64.

Chromosome behavior.—Both bivalent and quadrivalent associations of chromosomes appear at diakinesis and on the equatorial plate of the first meiotic division in microspore mother cells. Twenty-four bivalent and four quadrivalent groups are present in the diakinesis configuration shown in figure 1C. A polar view of the first meiotic equatorial plate presents five quadrivalent groups, the other chromosomes being associated as bivalents (fig. 1D). Lateral views of each plate examined showed some quadrivalents (fig. 1E, F), the number ranging from three to six. No trivalents or univalents were observed. A portion of the chromosomes on each equatorial plate usually disjoin in an irregular manner. A number of lagging chromosomes are

present in most anaphase figures of the first meiotic division (fig. 1G, H). In occasional figures (fig. 1H) there is some evidence that both members of a bivalent may pass to the same pole. The lagging chromosomes usually arrive at the poles in time to become incorporated in the daughter nuclei, and rarely during the interphase do chromosomes appear in the cytoplasm (fig. 11). The second meiotic division is likewise characterized by lagging chromosomes which often fail to be included in the spore nuclei (fig. 1J). These laggards may form the nuclei of small abortive microspores, or a small nucleus formed by one or more of these bodies may be included with a larger nucleus in a two-nucleate microspore (fig. 1K). A typical tetrad of four uninucleate spores is seldom seen. In macrosporogenesis the chromosomes behave as in microsporogenesis, and macrospores with extra small nuclei have been observed. Occasionally one and sometimes two of the ovules in an ovary possess embryo sacs that are apparently normal at the open flower stage. Pollen tubes are present in the cavities of ovaries collected 48 hours after tripping, and in two instances stages in fertilization were observed.

#### SUMMARY

Racemes of tripped flowers of *Medicago sativa* were subjected to heat treatment at an early stage in the development of the pro-embryo.

One tetraploid individual (2n = 64) was obtained from a population treated at 42°C. during the interval between 47 and 48 hours after pollination.

The tetraploid plant is similar to diploids in general habit. It possesses somewhat stouter stems and larger leaves and flowers. The stomata, epidermal cells, and pollen grains of the tetraploid are appreciably larger than those of the diploid.

The number of quadrivalents present at diakinesis in the microsporogenesis of the tetraploid plant varies from three to six.

Lagging chromosomes are present on both the heterotypic and homoeotypic spindles.

The induced tetraploid is highly sterile. Three offspring have been obtained from seeds resulting from self-pollination, all of which are tetraploid.

# LEAF POSITION IN AILANTHUS ALTISSIMA IN RELATION TO THE FIBONACCI SERIES $^{\scriptscriptstyle 1}$

## P. A. Davies

THE WRITER has shown that in Ailanthus altissima Swingle, although there appears to be a normal leaf arrangement, different phyllotaxis systems frequently occur (Davies, 1937). He also stated that the divergent angle of the apparent normal arrangement was approximately 135°, but offered no statistical proof. The present paper is a statistical study of the normal leaf arrangement and its relation to the Fibonacci series.

Schimper (1829, cf. Braun, 1831, p. 197, and Martin, 1833, p. 317), Braun (1831), and Bravais (1837), seeking an explanation for their studies on phyllotaxis, adopted the Fibonacci summation series (0, 1, 1, 2, 3, 5, 8, 13, etc.) and the principles of the "Spirals of Archimedes" to construct the Fibonacci fractional series (1/2, 1/3, 2/5, 3/8, 5/13, etc.) of leaf arrangement.

<sup>1</sup> Received for publication November 2, 1938.

Wiesner (1875) pointed out that under natural conditions the constant divergence expressed by the fractional series does not hold. In any system there is a variation in divergent angles. This postulate is supported by the studies of numerous workers on a great variety of plants.

Not only does the divergent angle fluctuate on any stem, but different fractional series may be present. Weisse (1926) found a change in phyllotaxis just below the floral structures in several species in the family Anonaceae. Schaffner (1926) has observed from studies on Cannabis sativa that frequently there is a change from opposite to alternate phyllotaxis near or in the inflorescence. Skutch (1927), working with Musca sapientum var. hort., observed that the phyllotaxis changed from about 2/5 in very young plants to 3/7 in half-grown plants and finally to 4/9 in the mature plants.

Toichi (1930) found that in Gardenia jasminoides there is a change from the opposite to a secondary whorl, which later may be replaced by the opposite. Bilhuber (1933) shows that in species of the families Cacteae and Euphorbiaceae beside the most often limit-divergence of 137° 30' 28", there also occur limit-divergences of 99° 30′ 43″, 77° 57′ 19″, and 64° 4' 43". Snow and Snow (1933, 1935) were able to alter the normal phyllotaxis ratio through experimental displacement of primordia at the apex in Lupinus albus and the diagonal splitting of the apices of Epilobium hirsutum. Of the 70 pieces of tissue formed by the split in Epilobium hirsutum, 50 regenerated strongly and grew new apices. Thirty-seven of the new apices immediately developed a spiral phyllotaxis, 5 were nearly decussate or becoming so, and 8 developed certain other arrangements. Davies (1936, 1937) has shown for Ailanthus altissima that frequently a new phyllotaxis system is established. The system which appears depends on the position of the first abnormally placed leaves.

A divergent angle has been sought which would express the most ideal divergence. Wiesner (1902) has indicated that the ideal angle is one in which the leaves are arranged in a single spiral sequence with a minimum overlapping. The mathematical expression of this "ideal angle" is 137° 30' 28". As the "ideal angle" is purely mathematical and based upon the Fibonacci fraction series, the angle is known as the "Fibonacci angle." There have been numerous attempts to correlate the divergent angle in actual counts with the theoretical Fibonacci angle. Church (1920) found in Sempervivum calcaratum and in Cobaea scandens, both of which have a 3:5 system, a divergent angle of 137° 38' 50" and 137.65°, respectively. The results of the observations of Schoute (1925) on Peperomia blanda, P. Langsdorfii, P. pulchella, and P. rubella show a divergent angle of about 140°. Salisbury (1931) gives the divergent angles for two winter rosettes of Ranunculus parviflorus. In both rosettes the average divergence was 137.3°. Snow and Snow (1931) found that the mean value of 52 divergent angles measured on Lupinus albus was 136.3°. Bilhuber (1933) found that in a large number of species in the families of Cacteae and Euphorbiaceae the divergent angles approximate the Fibonacci angle, although other divergent angles of lower values were present.

Cook (1914) states that the theories of phyllotaxis based upon leaf position on the mature stem or primordial positions at the developing stem apex do not give an adequate explanation from the botanical viewpoint of how the system originates. Van Iterson (1907) has found that in the seedlings in numerous species of plants the first two leaves arise at approximately 180° from each other or approximately 90° from the cotyledons. The divergent angles of the subsequent leaves do not approach the regular angles expressed by the fractional series until several leaves have arisen. Martinovsky (1930) found in various species of

Gagea that the leaves up to the fifth position have a distichous distribution; above that a secondary spirodistichous spiral appears. Toichi (1930) found in Gardenia jasminoides that both opposite and 3-whorled leaves occur; the opposite is the regular type, giving rise to the secondary whorls. Snow and Snow (1931) observed that the first two leaves in Lupinus albus arise at approximately 180° from each other, and then there is a gradual approach to the angle which can be considered normal.

The studies presented here by the writer are of the normal leaf arrangement in Ailanthus altissima with reference to: (1) position in a phyllotaxis series, (2) variation of the divergent angles, (3) closeness to which the mean divergent angle in actual counts approximates the Fibonacci angle, and

(4) the origin of the normal system.

MATERIALS AND METHODS.—In determining foliar position on the mature shoot, only the long, rapidly growing shoots were used. The shoots selected showed at least three complete foliar cycles. Since the shoots were selected after leaf fall, leaf scars were used as indicators of foliar position. A specially constructed apparatus was employed in measuring the divergent angles. The lower end of the shoot was securely fastened to a base platform and the upper part projected through an opening in the center of an adjustable platform. On the adjustable platform was a circle four feet in diameter divided into one-tenth degrees. The center of the circle was in the center of the opening through which the shoot projected. By moving the platform up or down, the divergent angles between foliar positions and between foliar cycles could be measured. The uppermost leaf scar was the initial point for measuring foliar divergence.

For determining the divergent angles at the developing apex, rapidly growing young shoots about 25 centimeters in length were selected. The shoots were long enough so that adjustment from the opposite to the whorled phyllotaxis had taken place. About two centimeters of the tips were removed, fixed in formalin-acetic-alcohol, as given by Chamberlain (1932), dehydrated by the Zirkle (1930) method, and embedded in paraffin. Serial sections were cut, stained with crystal violet, and mounted in balsam. Camera lucida drawings were made at different levels, so that the angular divergence of the leaf primordia and leaves through complete cycles could be determined. The divergent angles were measured in the camera lucida drawings by means of a protractor. The first definite leaf primordium, and not the primordial bulgings at the apex, was the initial point for the measurements.

Because it was impossible to obtain suitable transverse sections of resting buds, developing buds about 0.6 to 1.3 centimeters in length were used in measuring divergent angles in bud structures. Serial sections were made and the divergence angles measured in the same manner as described for the stem tip. The two outer cataphylls (A and A'; Davies, 1937) appear opposite each other. Cata-

phyll A was used as the initial point in divergent angle measurements.

The divergent angles of the cotyledons and leaves of young seedlings were measured in two ways, each serving as a check on the other. Photographs were made at different stages in seedling development, and the divergence angles as recorded on the photographs were measured with a protractor. Serial sections at different stages of seedling development were made and measured by the method described for the study of the divergence angles at the tips of rapidly growing young shoots. One of the cotyledons was used as the initial point in the divergent angle measurements.

Discussion.—The position of Ailanthus altissima in relation to a phyllotaxis series appears to be a 3/8 or 3:5 arrangement. The mathematical interpretation of the 3/8 arrangement would be that eight leaves compose a cycle. The leaves are distributed in three revolutions about the stem so that each leaf has a divergence of 135° and the first leaf of each cycle is directly superimposed over the first leaf of the preceding cycle. Wiesner (1875) and others have shown that the constant divergence of the fractional series does not hold, and in many cases great variations occur in both foliar and cyclic divergences. Salisbury (1931) has interpreted the 3/8 system that each leaf is not required to have an exact divergent angle of 135° and that the ninth leaf does not have to be directly superimposed over the first leaf, but that three members must invariably occur at each revolution of the stem. In all cases of Ailanthus in which the mean foliar divergence approximates the Fibonacci angle, three leaves occur in each revolution and eight leaves are present in three revolutions of the stem. The average divergence of leaf positions on mature shoots was 136.11°, or 1.11° above that of the 135° distribution of the 3/8 fractional series. The mean divergence of 685 angles measured at different areas on the plant (mature shoots, shoot tips, developing buds, and young seedlings) was 137.666° or only 2.666° greater than the constant angle expressed by the 3/8 arrangement. With a standard deviation of 8.583° from the mean divergence in the 685 angles measured, the 2.666° deviation from the 135° of the

Table 1. Angular divergence of three consecutive cycles on long shoots. First cycle indicates the divergent angle between the first leaf position (1) of the first cycle and the first leaf position (9) of the second cycle; the second cycle, between the first leaf position of the second cycle (9) and the first leaf position of the third cycle (17); etc. All measurements are in degrees.

		Foliar cycles	
Shoot number	First cycle 1-9	Second cycle 9–17	Third cycle 17-25

2	0.5	9.0	3.9
3	8.1	8.2	16.0

3/8 fractional series does not appear to be so large. Cyclic divergent variations in three consecutive cycles on three shoots are shown in table 1. These were selected at random from measurements on 12 shoots. In shoot number 1, the first cyclic divergence was 14.3°; the second, 3.7°; and the third, 8.3°. Shoots numbered 2 and 3 show similar large cyclic divergent variations. In the 36 cycles measured, the divergent range was from 0.5° to 30.3°, with an average of 10.31°. In none of the cycles

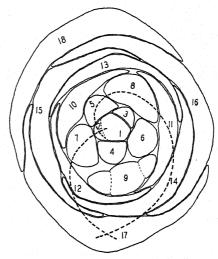

Fig. 1. Camera lucida drawing of a transverse section of a developing bud of *Ailanthus altissima*. Eighteen cataphylls, leaves, or leaf primordia are shown. Dotted lines are drawn through the approximate centers of units 2-5-8-11-14-17 and 2-7-12-17, respectively.

was the first leaf in each cycle directly superimposed over the first leaf of the preceding cycle, although in several cases the divergence was not great.

Church (1920, fig. XII) shows a drawing of a transverse section of the apex of Sempervivum calaratum. On the drawing appears a curve-tracing with a line passing through units 2-5-8-11-14-17-12-7-2. This he interprets to be a 3:5 phyllotaxis construction. Figure 1 shows a camera lucida drawing through the apex of a developing bud of Ailanthus altissima. The curve-tracing obtained by drawing a line through units 2-5-8-11-14-17-12-7-2 has the same logarithmic expression as Church has given for Sempervivum calcaratum and which he expresses as a 3:5 system. He also found in Sempervivum calcaratum and in Cobeae scandens, both of which have a 3:5 system, a divergent angle of 137° 38′ 50" and 137.65°, respectively. The mean divergence of the 685 angles in Ailanthus altissima after a normal phyllotaxis was established was 137.666° or 137° 39' 57". This very closely approximates the divergent angle in Sempervivum calcaratum and Cobeae scandens.

The data expressing the variations of the divergent angles and the relation of the cyclic averages of the divergent angles in normal distribution are presented in four groups of measurements: (1) leaf

positions on the mature stem, (2) primordial and leaf positions at the tip of rapidly growing long shoots, (3) leaf positions in developing buds, and (4) leaf positions on young seedlings.

Table 2 shows the divergent angles of foliar distribution and the averages of the angles of foliar distribution in two complete cycles on long mature shoots. The data were selected from the measurements of three complete cycles on 9 shoots. selections were made so that the first and last divergent angles approximated as nearly as possible the average for the two cycles and at the same time show both an angular variation within the cycle and a difference in the average variation in the two cycles on different shoots. The variations in the 216 angles measured was from a minimum of 124.7° to a maximum of 150.1°, or a range of 25.4°. The variation of the averages of the angles in the three cycles on the different shoots was from a minimum of 135.1° to a maximum of 140.3°, or a range of 5.2°. The average of the divergent angles for all measurements on the mature shoot was 136.11°.

The angles of foliar divergence and the averages of the angles for foliar distribution in a single cycle on each of four shoot tips selected from the 20 studied are shown in table 3. The selections were made so that the last divergent angle (8-9) approximated the average for the divergent angle in the cycle and at the same time showed both an angular variation within the cycle and a difference in the average variations between the cycles. The average variation in the 160 angles measured was from a minimum of 118.3°, to a maximum of 151.2°, or a range of 32.9°. The variation of the averages of the angles in the cycles was from a minimum 134.75° to a maximum of 141.70°, or a range of 6.95°. The average for all divergent angles measured was 137.51°.

The angle of foliar divergence and the averages of the angles of foliar divergences in complete cycles at the shoot tip of four developing buds after the average divergent angle approximated the Fibonacci angle is shown in table 4. The selections were made so as to show the variation of the divergent angle within the cycles and the average of the divergent angle in complete cycles. The angular variations in the 160 angles measured was from a minimum of 114.6° to a maximum of 157.5°, or a range of 42.9°. The variation of the averages of the angles in the cycles was from a minimum of 136.11° to a maximum of 141.65°, or a range of 5.54°. average for all divergent angles measured was 138.20°.

Table 5 shows the angular divergence and the averages of the angles of foliar divergence in the first complete cycles on four young seedlings after a normal phyllotaxis system was established. The data of the four seedlings shown in the table were selected from data on ten seedlings studied to show the variation of the divergent angles within the cycles and also a variation in cyclic averages. The angular variations in the 80 angles measured was from a minimum of 118.3° to a maximum of 165.4°,

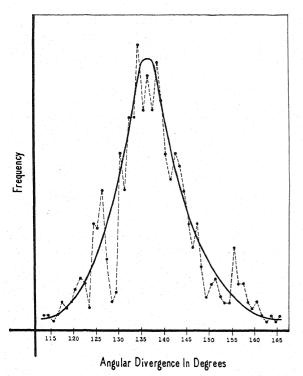

Fig. 2. Distribution curve of the divergent angle frequencies for 685 angles. The broken lines, which connect the frequency points, indicate the variation of the frequencies. The solid black line is a smoothing out of the frequency curve.

a normal phyllotaxis has been established than after one has been established.

Figure 2 shows a frequence distribution curve for 685 divergent angles from different areas of the plant (mature shoot, rapidly growing shoot tips, developing buds, and young seedlings). A broken line connects the frequence points and shows clearly wide frequency variation. The solid black line is a smoothing out of the frequency curve and shows a rather uniform distribution curve. The variations in divergent angles were from a minimum of 113.3° to a maximum of 165.4°, or a range of 52.1°.

It is clearly evident from the data presented that wide variations of divergent angles are present on the same shoot and on different shoots, even after the normal phyllotaxis system is established. This is in agreement with the postulate of Wiesner (1875) and others that a constant divergence as expressed by the fractional series is not maintained under natural conditions.

The closeness to which the mean angular divergence approximates the Fibonacci angle is given from calculations on data presented in figure 2. The mean divergence of the 685 angles measured after a normal phyllotaxis system was established is 137.666° or 137° 39′ 57″. Comparing this with the Fibonacci angle (137° 30′ 28″), a difference of only 0° 9′ 29″ or .159° is evident. The standard deviation from the mean is 8.583°. It is interesting to note that with such a wide deviation the mean divergent angle should so closely approximate the Fibonacci angle. It is clearly the result of the particular group of angles measured, for any other group of measurements, even with a greater number of angles, may give a much greater mean divergence.

Cook (1914) states that the theories of phyllotaxis based upon leaf position on the mature stem or primordial positions at the developing apex do not give an adequate explanation from the botanical viewpoint of how the system originates. Van Iterson (1907) for numerous plants, Martinovsky (1930) for Gagea, Toichi (1930) for Gardenia jasminoides, and Snow and Snow (1931) for Lupinus albus, show that the first leaves to appear have a decussate distribution and that gradually there is an approach to the angle which may be considered normal. The normal phyllotaxis system in Ailanthus altissima as expressed on the mature shoot or the developing stem apex (tables 2 and 3) has its origin in either bud or seedling development.

Table 6 shows the origin of the normal system and the angular divergence for the first nine cataphylls to appear in bud development. The four examples were selected from 15 buds studied in order to show the variation in divergent angles and the level at which a normal distribution was established. The outer cataphylls (A and A') develop opposite each other or at an angle of approximately 180°. B, the third cataphyll to develop, appears basically and approximately equally distant (90°) between A and A'. B', the fourth cataphyll to appear, develops either in a clockwise or counter-

clockwise direction from B.2 Its divergent angle (shown in the table by B-B') in the four examples shows a variation from 154.7° to 179°. The average for all 15 buds was 162.77°. The divergent angle of unit 5 (B'-1) was the smallest angle in the bud. It was the smallest consistent angle of all divergent angles measured. The average for the 15 buds was 77.4°. Above the fifth unit, the divergent angles tend to gradually approach an angle comparable to the Fibonacci angle. The normal distribution, approximating the Fibonacci angle, was not established at the same level in all buds. In bud number 1 the first angle to approach the Fibonacci angle was unit 9 (4-5); in number 2, unit 8 (3-4); and in numbers 3 and 4, unit 7 (2-3). In the 15 buds studied, four approached the Fibonacci angle in the 7th units, 7 in the 8th unit, and 4 in the 9th unit.

The cotyledons and foliar distributions in the first twelve units to form in three developing seedlings and the establishment of a normal phyllotaxis are shown in table 7. C and C' are the two cotyledons, and they appear opposite or at an angle of approximately 180°. The first two leaves to develop appear opposite and approximately 90° from the cotyledons. The third leaf (2-3) is superimposed over one of the cotyledons (cotyledon C) or approximately 90° from leaf 1 or 2. The fourth leaf appears in an angle of least influence between either leaf 1 and cotyledon C or leaf 2 and cotyledon C. The average for the divergent angle for leaf number 4 in the three shoots shown in the table is 169.26°. Above the fourth leaf there is a gradual approach toward an angle which may be considered normal. In seedling number 1 this angle was established by the seventh leaf, while in 2 and 3 by the ninth leaf. In the 20 seedlings studied, two devel-

<sup>2</sup> A transverse drawing of a bud and the designation of the symbols A, A', B, and B' are given in a previous paper (Davies, 1937).

oped the normal arrangement with the seventh leaf; six with the eighth leaf; seven with the ninth leaf; four with the tenth leaf; and one with the eleventh leaf

The data show that the development of the normal leaf arrangement in Ailanthus is gradual. Beginning with the one-half or decussate distribution there is a gradual approach to the normal, which approximates the 3/8 distribution. This gradual approach from the decussate to the normal arrangement is in agreement with the results of Van Iterson, Martinovsky, Toichi, and Snow and Snow.

#### SUMMARY

The position of Ailanthus altissima in a phyllotaxis series appears to be a 3/8 or 3:5 arrangement—that is, the mean foliar divergent angle approximates the 135° distribution of the fractional series.

Large variations in divergent angles occur even on the same shoot. The variation of angular divergence in 685 measurements on mature shoots, rapidly growing shoot tips, developing buds, and young seedlings was from a minimum of 113.3° to a maximum of 165.4°, or a range of 52.1°.

The mean angular divergence of 685 foliar positions was 137.666° or 137° 39′ 57″. This very closely approximates the Fibonacci or "ideal angle" of 137° 30′ 28″. The standard deviation from the mean was 8.583°.

The normal phyllotaxis system has its origin in the one-half or decussate arrangement in bud or seedling development. The normal system was established in bud development between the seventh and ninth units and in seedling development between the seventh and eleventh units.

## A COMPARISON OF TWO QUANTITATIVE AVENA TECHNIQUES IN THE DETERMINATION OF 3-INDOLE ACETIC ACID <sup>1</sup>

Richard H. Goodwin

A BIOLOGICAL method for the quantitative determination of minute amounts of auxin was described by Went (1928), who employed as a test object the coleoptile of Avena sativa. Although other species of plants have since been used with some success, none of them has obtained such universal popularity. Went's method employs seedlings grown in water cultures at a high (85-90 per cent) relative humidity. Boysen Jensen (1935, 1937), however, has described a somewhat different Avena technique—a further development of the method used by Nielsen (1924)—, in which the plants are cultivated in soil at a much lower (30-45 per cent) relative humidity. He points out that the plants, although somewhat more variable, are also more sensitive when grown under these conditions. Since these two methods of auxin assay have both been used up to the present time, it was thought worth while to carry out a series of experiments comparing their relative advantages.

In the following investigation the activity of several concentrations of 3-indole acetic acid was tested from time to time over a period of several months both by the method of Went and by that of Boysen Jensen. A fresh standard solution was made up each time by dissolving 5 mg. of 3-indole acetic acid (LaRoche) in 5 cc. of peroxide-free ether and then adding 500 cc. of distilled water. Of this standard solution 1 cc. was diluted with distilled water to twice the concentration to be tested, and 5 cc. of this solution were added to an equal volume of 3 per cent agar at 60°C. Thimann and Schneider (1938) have demonstrated that direct mixing of 3-indole acetic acid solutions with melted agar is preferable to soaking agar blocks in the solution. Of the agar mixture 2.5 cc. were poured out on a 5 × 5 cm. glass plate, and as soon as the agar had hardened, the blocks  $(2 \times 2 \times 1)$ mm.) to be used in the tests were cut out with parallel knives. Although blocks of 4 mm.3 are smaller than those used by many workers, difficulty

1 Received for publication September 24, 1938.

This investigation was carried out in the Plant Physiology Laboratory of the University of Copenhagen during the tenure of an American-Scandinavian Foundation Fellowship. The writer is deeply grateful to Professor P. Boysen Jensen for making available the facilities of his laboratory and for his unfailing interest in the work.

due to drying out of the blocks was not experienced.

Victory oats, a Swedish variety generally used in phytohormone research, served as the test object. In Copenhagen Victory oats have recently been substituted for the variety Gul Naesgaard. In comparing the soil-culture technique of Boysen Jensen (1935) with the water-culture technique of Went (1928), two series of tests were carried out. For the sake of brevity, the cultural conditions and technical details of the two methods as followed in this investigation are outlined in table 1. The dark room was maintained at  $23 \pm 1^{\circ}\mathrm{C}$ ., a temperature intermediate between that used by Went and that used by Boysen Jensen.

The magnitude of each curvature was determined in two ways: (1) the angle between the tip of the coleoptile stump and the uncurved base was measured with a protractor from shadow prints which were made on bromide paper at the end of each test (method of Went), and (2) by matching the concave surface of the curved portion of the coleoptile with the corresponding arc in a graded series (radii of curvature ranging from 6 to 80 mm.; lengths marked off in mm.) drawn on a scale (Boysen Jensen, 1935) l, the length of the curved portion of the coleoptile, and r, the radius of curvature, were measured directly. The angle of curvature,  $\psi$ , was calculated from the formula,  $\psi = 360 l/2 \pi r$ . In Copenhagen curvatures are measured by d, the difference in length between the convex and concave sides of the coleoptile, which can be calculated from the formula, d = tl/r (Purdy, 1921), where t, the thickness of the coleoptile, is taken as a constant. By substituting tl/r for d in the formula d = $\psi$  2  $\pi$  t/360 (Boysen Jensen, 1935), the formula,  $\psi = 360 \ l/2 \ \pi \ r$  can be derived.

In forty tests the mean difference between the larger and smaller curvatures obtained by each method was  $1.01^{\circ} \pm 0.19^{\circ}$ . This is not a systematic error, since the values for the measured angles averaged only  $0.16^{\circ} \pm 0.19^{\circ 2}$  less than those for the angles calculated by the second method. Although Dolk (1930) has shown that the curvatures of Avena coleoptiles are not true arcs of circles and, hence, that the measured value of r can be only an approximation, any error thus introduced

<sup>2</sup> The standard deviation of the mean is given.

is rather insignificant in the determination of large angles. In the case of small angles, on the other hand, direct measurement from shadow prints is more accurate, especially since values of r greater than 80 mm. are neglected. Furthermore, shadow prints afford permanent photographic records not only of the magnitudes but also of the shapes of the curvatures.

The curvatures obtained by each method (outlined in table 1) for five concentrations of 3-indole acetic acid and the dates of the tests are given in table 2. Each value is the mean of 12 plants. It may be seen that, for a given concentration, curvatures obtained with Boysen Jensen's technique were nearly twice as large as those obtained with Went's method. There are probably at least three factors partially responsible for this difference: (1) greater sensitivity of the soil-grown plants, (2) a 35- to 40- minute difference in interval between decapitation and application of the agar block (or IDP, see Schneider and Went, 1938), and (3) a 70-minute difference in photographing time. The standard deviations of the averages in table 2, due both to individual variations in the plants and to slight changes in conditions from day to day, are of nearly the same magnitude with each method. Hence, the coefficient of variability of the averages is considerably smaller for tests with Boysen Jensen's technique. Juel (1936) obtained comparable variation in tests with this method in the same laboratory. It should be pointed out, however, that the standard deviations of individual tests with Went's method are larger than those obtained by Went (1928), van der Weij (1931), et al. With more careful control of the temperature and humidity, the variability of both methods might well have been reduced.

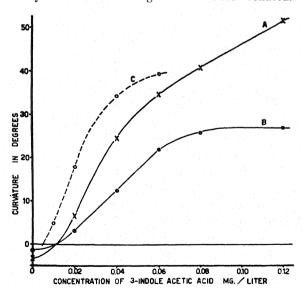

Fig. 1. Curvature of Avena coleoptiles for various concentrations of 3-indole acetic acid. A, soil-culture technique of Boysen Jensen (1935). B, water-culture technique of Went (1928). C, deseeded, water-culture technique of Skoog (1937).

TABLE 1.

Soil-culture technique of Boysen Jensen (1935) Water-culture technique of Went (1928)

Large seeds selected; husks not removed.

Grains soaked for 24 hours in 5 mm. of water at 18°C.; exposed to daylight.

Large seeds selected and dehusked.

Seeds soaked for 3 hours; then laid out, groove down, on wet filter paper in petri dishes for 24 hours at 22-24°C.; exposed to some red light.

Seeds planted in glass holders with the roots in tap water (pH about 7.4).

Grains planted vertically in glass vials ( $20 \times 100$  mm.) filled very loosely with sifted, sandy loam (water content 26-28 per cent (Juel, 1936)), the apex just above the surface of the soil. The soil may be used repeatedly for about a month if kept in a covered container and moistened after each test.

Plants grown in a dark room at 22-24°C. (Boysen Jensen (1935) used a temperature of 21-21.5°C.) under containers for the first 48 hours and in partially-covered boxes at 35-45 per cent relative humidity for the last 24-28 hours.

Tests carried out 72-76 hours after planting, when the coleoptile tips were 18-20 mm, above the soil surface.

3 mm. of the coleoptile decapitated by nicking the  $b \ ro \ a \ d$ , slightly-concave side with a razor and breaking off the tip. The stump was moistened with a drop of water.

Agar block 4 mm.<sup>3</sup> placed on the broad, concave side within 5 minutes of decapitation. Plants placed under 2-liter bell jars lined with wet filter paper during the test. (Tests with the block placed on the narrow side proved to be more variable.)

Curvatures measured 180 minutes after application of the agar blocks.

Plants grown in a dark room at 22–24°C. (Went, 1928, and subsequent workers have used 25°C.) in a moist chamber with a relative humidity of about 85 per cent.

Tests carried out 48-52 hours after planting when the coleoptiles had reached a length of 20-30 mm.

4-5 mm. of the coleoptile decapitated by nicking a narrow side and breaking off the tip. The primary leaf pulled loose. Excess water removed from the stump with filter paper.

Agar block 4 mm.<sup>3</sup> placed on the narrow, cut side 40 minutes after decapitation. Plants kept in a moist chamber at about 85 per cent relative humidity throughout the test.

Curvatures measured 110 minutes after application of the agar blocks.

The average curvatures in table 2 are plotted against concentration of 3-indole acetic acid in figure 1. The relation between curvature and concentration for Went's method (fig. 1B) was a linear

one with concentrations from 0.01 to 0.06 mg. of 3-indole acetic acid per liter, but strict proportionality was not obtained. This suggests that such proportionality should never be assumed under a new set of conditions until it has been experimentally demonstrated. Thimann and Schneider (1938) point out that the shape of the curvature-

concentration curve for 3-indole acetic acid may be greatly modified by alterations in the number and timing of the decapitations and the concentration of the agar. If proportionality between curvature and concentration does not hold, the amount of active substance in an unknown solution may still be estimated from a curvature-concentration curve.

 $<sup>^{\</sup>rm a}$  1  $\gamma$  = 0.001 mg.  $^{\rm b}$  Approximately the maximum angle.

As suitable absolute units, van Overbeek (1938) suggests 3-indole acetic acid equivalents per liter.

With Boysen Jensen's method the curvature-concentration relationship followed a smooth curve between 0.01 and 0.12 mg. per liter (fig. 1A). A calculation must be made in order to express the amount of active substance in an unknown solution in arbitrary units. Boysen Jensen (1937) uses "WAE," the amount of active substance dissolved in 100 cc. of 1.5 per cent agar which, when applied unilaterally to Avena coleoptiles in 4 mm. blocks at a temperature of 21–22°C., will produce in three hours a curvature with a d value of 1 mm. (or a curvature of approximately 38 degrees). Quantitative determinations can be made over a greater range of concentrations with this method under the conditions described.

With both Went's and Boysen Jensen's methods there appears to be a threshold concentration at about 0.01 mg. per liter, below which no activity can be detected. Among various recent modifications of Went's original technique the deseeded method of Skoog (1937) may be used as a more sensitive test for very low concentrations. Curvatures obtained five hours after application of the agar blocks for water-cultured plants deseeded 18 hours before the tests are given in table 2 and plotted in figure 1C. Under these conditions the threshold concentration is about 0.005 mg. per liter. Skoog (1937) reports still lower threshold values. The deseeded test has been used at Utrecht with great success by Koningsberger and Verkaaik (1938), who showed that the method yields highly reproducible results.

The speed with which tests can be carried out is an important practical consideration. Perfect test plants can be obtained either from soil or from water cultures, but crops of water-grown plants exhibit greater uniformity. For this reason it is not necessary to discard so many water-grown plants before the tests and hence there is an economy of time. The total time required for all operations as outlined in table 1 averages approximately 35 minutes per test of twelve plants for Boysen Jensen's method and about 30 minutes per test for Went's method. If deseeded plants are desired, about 35 minutes per test are required. Permanent records of the curvatures in the form of shadow prints may be obtained by either method. Soilgrown plants are easily handled for photographing by arranging the vials in racks of twelve; but measuring them in this way will further increase the time per test. Calculating the angle from measurements of l and r has the advantage that computation of the results (greatly expedited by means of a table giving angles for values of l and r) can be obtained within five minutes of the end of the test.

Water cultures cannot be conveniently handled in considerable numbers except in a constant-temperature, air-conditioned dark room with a high relative humidity. Where such facilities are not available, the soil-culture method offers a ready means of making auxin determinations. There are two objections to the use of soil, however: (1) the impossibility of reproducing exactly the same conditions in different laboratories, and (2) the difficulty in mantaining the proper moisture-content of the soil. Water cultures obviate these difficulties and lend themselves more easily to experimental modifications such as removal of the primary leaf, deseeding, and alterations of the culture medium. In actual practice it is frequently impossible to compare critically the results obtained in different laboratories with water-cultured test plants, since refinements in the technique are constantly being proposed, no one of which has yet been universally accepted (Avery, Burkholder, and Creighton, 1937; Skoog, 1937; Went and Thimann, 1937; Schneider and Went, 1938; et al.).

## SUMMARY

A comparison of the accuracy and utility of the Avena test in the quantitative determination of 3-indole acetic acid as carried out by Went with water-cultured plants and by Boysen Jensen with soil-cultured plants has been made. Each method offers certain advantages. In a laboratory with no facilities for precisely controlling the humidity of the constant-temperature dark room, Boysen Jensen's test with soil-grown plants may be most simply, accurately, and expeditiously used. In a completely air-conditioned dark room, however, Went's test with water-cultured plants can be more speedily executed and more readily standardized and modified. The relative accuracy of the two methods under such conditions has not been investigated.

## SOME OBSERVATIONS ON SEXUAL DIMORPHISM IN CAREX PICTA 1

## J. Louis Martens

It is desirable to clarify the problematic relationship of the grasses and sedges. In order to do that, it is appropriate that more sedges be investigated, since heretofore the members of the Gramineae have been more popular subjects for study than have the Cyperaceae. Because of their vital importance, grasses have been studied extensively from both the practical viewpoint and from the standpoint of pure science. The sedges, however, are of incomparable economic importance, and much remains to be known about them before they will be understood as well as the grasses. In an effort to supplement the studies of the Cyperaceae, Carex picta Steudel was chosen for investigation.

Fig. 1. A characteristic plant of Carex picta, Monroe County, Indiana.

<sup>1</sup> Received for publication September 29, 1938. I wish to acknowledge appreciation to Prof. Paul Weatherwax, at whose suggestion this problem was selected, and to Dr. D. M. Mottier under whose direction a part of the work was done. I am also grateful for advice and courtesies extended by other members of the department. Carex picta is a favorable sedge for study. It is typical of the genus Carex in many ways, but it is dioecious. The latter characteristic, however, lends itself to the study of sexual expression in the sporophyte, a subject of general interest. Then this species is sufficiently abundant near Bloomington to have facilitated many collections and field observations.

This study, which was begun in the spring of 1933, includes observations on several different aspects of the plant. Analyses of the flowering habit bring out the stability of its dioecious character. Ontogenetic studies on the floral units portray the relationship of the floret components of each sex and throw light on the comparative degrees of specialization in the staminate and pistillate spikelets. The origin and development of the micro- and megagametophytes, as compared with other species of Carex, complete the observations.

Habit and inflorescences.—This Carex is a tricarpellate species limited to local distribution in the eastern part of the United States. It should not be confused with either of two bicarpellate Carices (Kükenthal, 1909), one native to New Zealand, the other to Asia, to which its Latin binomial has been applied by some authors. It is a common sedge in southern Indiana in the residual soil of the Borden, a sandy shale formation of lower Mississippian age.

C. picta grows as a grass-like plant. It is a vernal perennial species and appears in characteristic tufts (fig. 1) by which it may be recognized in all seasons. These tufts may vary in diameter from a few inches to more than two feet, the male and female plants being practically indistinguishable without inflorescences. During anthesis the male plants produce dark-colored, clavate spikes, each on a filiform scape (fig. 2). The female inflorescences are similar but more slender and of a uniform diameter (fig. 3).

The vegetative and fertile shoots of both sexes grow from an underground stem. They are arranged in a circle, the center of which appears dead. This "fairy ring" effect suggests a radiating rhizome

Fig. 2-3. Inflorescences.—Fig. 2. Male.—Fig. 3. Female.

system physiologically comparable with the radiating growths of mycelium responsible for the "fairy rings" of mushrooms, but it is really brought about in a very different way. The culms grow from the tips of underground branches, but the rhizomes tend to branch often and dichotomously, and the result is that secondary branches fill in an approximately 90' angle (fig. 4, a) formed by the first two primary branches. Secondary branches exterior to this angle tend to complete the circle. Although the system appears nearly perfect above ground, it often develops from a roughly subcircular rhizome system (fig. 5).

This combination of the dichotomously branching rhizome system and its culms is conveniently referred to as a "clump." Inasmuch as a plant must develop under suitable conditions to form a characteristic clump, and it requires several years for one to grow into a ring, all individuals do not appear exactly characteristic. Most of the clumps are distinctly segregated growths. However, they may grow adjoining, and at times the rhizome systems of two separate plants grow interwoven so as to form one clump. When plants of opposite sex are found making up one clump, it is aptly spoken of as a "mixed clump." It should not be forgotten, nevertheless, that in speaking of a mixed clump two plants are involved. This has been verified repeatedly by digging up clumps of this nature and separating the male and female rhizome systems.

The general floral expression of *C. picta* deviates very little from the descriptions of the species found in manuals. The male flower consists of three stamens apparently attached directly to the

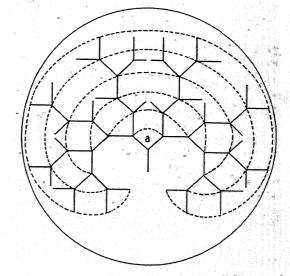

Fig. 4. A graphic representation of the dichotomously branching rhizome system. The solid lines represent the progressive development of the rhizome;  $\alpha$  is the angle formed by the first two primary branches, and the dotted lines represent expansion of the clump margin.

ixis of the inflorescence in a horizontal line. No rudiments of a perianth or gynoecium have been observed. Before anthesis the flower is covered by a subtending bract, and the 30 to 60 florets are aggregated spirally in a compact spike. The spikes occur singly on individual scapes (fig. 2).

The pistillate flower is as simple as the staminate but more difficult to interpret. It consists of a stipitate, tricarpellate pistil made up of a trigonous ovary, a slender style, and three filiform stigmas. There are no vestiges of stamens, or of a perianth.

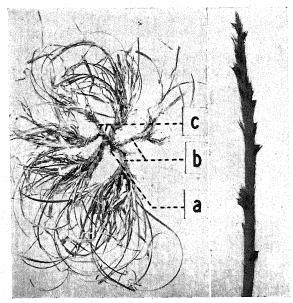

Fig. 5-6.—Fig. 5 (left). Rhizome system with roots removed; a, primary stem; b and c, secondary branching systems formed from first two branches.—Fig. 6 (right). Pistillate spikelets in a predominantly staminate inflorescence of Carex crinita.

Instead of being attached directly to the primary axis, however, the pistillate flowers are produced singly on short, inconspicuous, but definite secondary axes, which are located in the axils of spirally arranged bracts. Both the gynoecium and the dwarf axis are enclosed by bracteole, the margins of which are united forming a rather loose-fitting, sac-like structure with a small distal bidentate aperture. Since the pistil is much larger than its axis, this foliar envelope assumes the shape of the ovary, and the style and stigmas are exerted through the opening in its top. Inasmuch as the components within this floral unit are concealed by the subtending bract until maturity, the external appearance of the inflorescence (fig. 3) is similar to that of the staminate spike.

This axillary floret, consisting of a branch of limited growth, a bracteole, and a pistil, has been designated as a spikelet by several observers who have made morphological and anatomical studies of the Cariceae. Among the morphological investigations of *Carex* and related genera, the studies of

the bracteole have been especially prominent. According to Baillon (1894), it has been known under sixteen different names. At present it is known as the perigynium in American floras and as the utriculus (utricle) in most European literature. In this discussion the terms bracteole and perigynium may be used interchangeably. The former term, bracteole (Arber, 1925), however, applies to the first leaf on any branch of an inflorescence regardless of the order of the branch, while the term perigynium refers specifically to this special bracteole which accompanies each pistillate flower.

In many other species of Carex, where branching occurs in the reproductive shoot so that several spikes or spikelike inflorescences occur on a common axis, a bracteole is found sheathing the base of the peduncle of each inflorescence. Since more than one inflorescence is rarely found on a scape of C. picta, not many bracteoles of the latter type

have been available for observation.

FLORAL EXPRESSION.—Since stamens have long been associated with maleness and carpels with femaleness, diclinous flowers and dioecious plants have come to be known as male and female. This distribution of stamens and carpels in separate flowers is often followed with greater interest than when the flowers are perfect; and when bisexual flowers are found on typically monoecious or dioecious plants, or when sporophylls are observed with characteristics of both stamens and carpels, such plants and sporophylls are looked upon with special interest. At first these unusual conditions were described as teratological forms, but more recently they have been regarded as representatives of gradations in sexual expression. Many monoecious species have been pointed out (especially by Schaffner, 1921) in which sexual gradations of this type Similar observations (Schaffner, 1919; Yampolsky, 1920) have also illustrated bisexual tendencies in dioecious individuals. If these "abnormalities" represent intermediate sexual expressions, they may be conceived as common,2 although more frequent in some species than in others, and perhaps where they are thought not to occur, systematic studies will bring out an almost universal distribution among flowering species.

Within the genus Carex are a great many variations in sexual expression, and this unstable arrangement of staminate and pistillate flowers is known for both bicarpellate and tricarpellate forms. Investigators have pointed out this condition from time to time in discussing both monoecious and dioecious individuals. Holm (1921) found variations common enough in his Aeorastachyae, a group of monoecious Carices, to show the distribution of staminate and pistillate spikes by means of tables. One of the species constituting this group, C. crinita Lam., also illustrates especially well the irregular distribution of the two sexes in an individual in-

<sup>2</sup> Reference is made here to plants with diclinous flowers in which the two extremes in sexuality are characteristic, and not to the monoclinous where a bisexual expression is typical.

florescence. Figure 6, in agreement with Holm's description of floral expression in this Carex, brings out vividly one of the possible irregularities. In addition, Holm (1900) pointed out that sexual variation could be used as an aid in distinguishing C. circinata C. A. Mey from C. lejocarpa (leiocarpa) C. A. Mey when discussing the affinities of the two species. All specimens of C. circinata were found to be androgynous, while those of C. lejocarpa were found to be both dioecious and androgynous. It is also interesting that Kükenthal (1909) found it necessary to list monoecious varieties for many of the dioecious species which he recognized. Then Arwidsson (1928), after examining representatives of the Carex dioica-group, has discussed the prevalence of androgynous forms in Scandinavia as opposed to their rare occurrence in England. In contrast with this instability, it was noticed, when collecting inflorescences for morphological investigation, that C. picta was seemingly strictly dioecious. In order to secure data which would express the actual trend of sexuality in this species, the inflorescences of specific plants were examined during successive flowering periods.

This analysis of floral expression included 82 clumps, 79 unisexual and three mixed, the three mixed and 69 unisexual clumps being studied in the native habitat, and the remaining ten plants being grown inside and followed under greenhouse conditions

A very slightly grazed open woodland about two miles north of Bloomington, Indiana, was selected for field observations. In the spring of 1934, 23 clumps were plotted on a northwest-facing slope and 49 on a west-facing one. The ten clumps, five staminate and five pistillate, studied under artificial growing conditions were not transplanted to the University greenhouse until the following fall, and observations were not continued over as long a period as they were outdoors. Nevertheless, there were more data secured from each of these plants than were obtained from each plant in the native habitat, since those indoors flowered three to four times a year.

Each of the clumps of Carex selected in the native habitat in 1934 was marked with a metal marker, and floral analyses were continued during the flowering periods of the next four years. Thirty-two were originally recorded as purely staminate, 36 as pistillate, and three as mixed. The plants included in this survey, irrespective of sex, produced an average of 15-20 inflorescences each year. The number of inflorescences for both male and female plants, however, varied greatly. As many as 65 were recorded for one staminate clump, while 59 was the largest number found on a pistillate plant. The average number of inflorescences per staminate clump was consistently about one and a third times as large as that produced by the pistillate. It was also observed that plants of each sex did not produce inflorescences year after year without exception. Plants which failed to flower are referred to as "sterile."

Twenty-four (three-fourths) of the truly male clumps developed purely staminate inflorescences during all five seasons. Four staminate clumps were sterile one out of the five years. Three of this number were known to resume their original sexual expression; the fourth failed to flower during the final year of the survey. There were two male clumps for which data were incomplete: One of these was overlooked in 1936; in the case of the other the marker was "borrowed" in 1936 and not returned. Two other staminate clumps were found to produce an androgynous inflorescence. This type of inflorescence was observed on one of these plants in 1937 and in 1938. This plant was not an exceedingly vigorous one. In 1937 the androgynous inflorescence was the only one produced, but in 1938 four staminate inflorescences were produced in addition to the androgynous one. Each of the bisexual inflorescences of this clump was characterized by a single pistillate floret in the axil of the lowest bract. The other plant with the hermaphroditic tendency was observed with an androgynous inflorescence only in 1938. This plant, in contrast with the former, was vigorous and produced 42 staminate inflorescences in addition to the androgynous one. In this instance two pistillate spikelets occurred in the bisexual inflorescence, one in the axil of each of the two lowest bracts. One of the clumps, which was considered staminate during the first two years of the floral analysis, flowered as a mixed clump during the last three. At first it was thought that a partial reversal of sex had taken place. After careful observations, however, it was concluded that the clump was originally a mixed one and that the pistillate constituent had remained sterile during the first two years of the floral analysis.

Twenty-two of the clumps originally marked pistillate produced solely pistillate inflorescences from 1934 to 1938, inclusively. Thirteen of the pistillate clumps became sterile at some time during the five year survey. Ten of this number remained sterile for one year and then renewed production of the flowers originally recorded for them. The eleventh was sterile in 1936 and died before the next flowering season. The other two, having become sterile, failed to flower during two consecutive years. One of these produced pistillate inflorescences after the period of sterility; in the case of the other, the second sterile season came the last year of the floral analysis. One pistillate clump was overlooked in 1936, but during the remaining four years it was typically pistillate. Unlike the male plants analyzed, this group showed no sexual intergrades, neither gynaecandrous or androgynous (Mackenzie, 1931) inflorescences being observed in them during the survey.

The Carex plants making up the mixed clumps behaved in much the same way as did those growing independently. One of the three clumps produced

egularly male and female inflorescences each year; n another the pistillate constituent remained sterile n 1937 and then flowered in 1938. Since the third lump was not located in 1935, no datum is available for that year. In 1936 both of its components were sterile. During the last two years of the survey, female inflorescences were developed, but an expression of the male element was still not apparent.

The ten plants transplanted to the greenhouse grew well under these conditions. A change in environment and transplanting has been correlated with alteration of sexual expression in some plants,

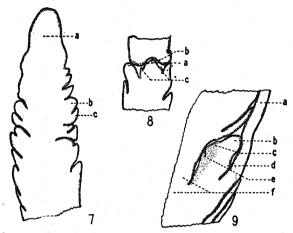

Fig. 7-9. Primordia of pistillate inflorescence.—Fig. 7. but, although in this instance the plants flowered three to four times a year, nothing of that nature was recorded. All the plants remained unisexual, and no bisexual inflorescences were observed.

From these observations, C. picta in this locality may be described as being remarkably uniform in its sexual expression, and the occurrence of the androgynous inflorescences brings out the fact that, although the species is remarkably constant in its sexual expression, it is not entirely without sexual intergradations.

The occurrence of sterility in the sequence of years is looked upon with interest. It, however, seemingly does not affect nor does it seem to indicate a reversal of sexual expression. That a change has taken place within the plant which upsets its potential sexual expression is realized. This condition, described by Schaffner as neutral, is undoubtedly not without significance, but in this species it could not be associated with the production

of androgynous inflorescences and sexual gradation.

ONTOGENY AND VARIATION IN FLORETS.-The interpretation of the relationship of the perigynium to the pistillate flower in Carex, as is presented in the discussion on the floral units of Carex picta, was first proposed by Kunth in 1835 (Eichler, 1875) after studying a species of Schoenoxiphium, and his explanation has received general support in the past century by such investigators as Townsend (1873), Eichler (1875), Pax (1885), Baillon (1894), Holm (1896), Kükenthal (1909), Snell (1936), and others. For the most part, they have stressed the evidence as brought out by the comparative morphology of the spikelets of Schoenoxiphium, Kobresia, Uncinia, and Carex, all genera of the tribe Cariceae. Townsend (1873), however, states that this same interpretation of the floral unit may be illustrated by deviations in the bracteoles of Carex glauca and possibly C. riparia. Later, Holm (1896) duplicates Townsend's explanation in citing transitions between the "ochrea" and the "utriculus" in Carex cladostachya Wahlbg. In addition to other illustrations within the genus, the cladoprophyllum and utriculus, as used by Kükenthal (1909) in the floral diagnosis of several species of Carex, are a notable supplement to the interpretations of Townsend and Holm. Then Snell (1936) has recently cited anatomical evidences along with a review of the explanations based upon comparative morphology.

The ontogeny of the spikelets of Carex picta brings out another interesting correlation with the explanations of the pistillate floret of Carex based on other evidence. A study of serial sections of this species shows, as early as the middle of August, embryonic inflorescences with the primordia of bracts and axillary axes near their tips. The arrangement and shape of these newly formed organs are typical for the beginnings of leaves and their axillary axes (fig. 7). Both are rounded on top, that of the bract being ridge-like and that of the axis being short columnar. Each primordium at first appears as a slight undulation. When that of the axillary structure is slightly longer than broad, the primordium of the perigynium becomes dis-The beginning of the perigynium is a cernible. collar-like ridge with two collateral prominences (fig. 8) which tend to slope downward adaxially and abaxially, the higher tangential edge usually being next to the bract primordium. Of the three initial structures the bract grows most rapidly. When the bract has grown to twice the height of the lateral axis, the primordium of the gynoecium is readily perceptible above that of the perigvnium on the side of the rachilla next to the rachis (fig. 9). The newly formed, obtusely hemispherical primordium is easily recognized by cells with extremely dense cytoplasmic contents. It soon becomes trilobate, each lobe representing a carpel. The lobes are arranged in a triangle with two transversely adjacent ones uppermost. Toward the end of Sep-

tember the three embryonic carpels assume the upward course of growth taken by their parental axis. At this time the carpels and their axis (fig. 10) are about equally prominent, and the primordium of an ovule appears within the triangle formed by the carpels. The gynoecium develops rapidly, and usually by the middle of October it becomes several times as large as the rachilla (fig. 11), the upper portion of the columnar constituents elongating to form the style and stigmas, and the basal portions developing into the trigonous overy. Within the one-celled ovary, the basilary ovule now usually exhibits two integuments and a megaspore mother cell. At this age also the body of the perigynium envelops the major portion of the ovary, the collateral lobes rising slightly above it. The entire spikelet, however, remains covered by its subtending bract.

A transverse section through the base of a nearly mature pistillate floret (fig. 12) shows that the gynoecium has followed the course of development indicated in the embryonic stages. The vascular

strands and the lobes corresponding to the carpels show that one carpel is located next to the main axis of the inflorescence and two on the other side. The perigynium has two large vascular strands, which traverse the lateral lobes and aid in determining the orientation of the spikelet and its components.

The preceding has established the sequence in which the primordia of the parts of the pistillate floret appear in Carex picta. These primordia have been followed as they continued their development. Although the oldest examined are still immature, these spikelets appear to be characteristic for the species; and the succession and behavior of the primordia from which they are formed are in harmony with the interpretation of the pistillate floral units of the Cariceae, as has been established and maintained by other methods of investigation.

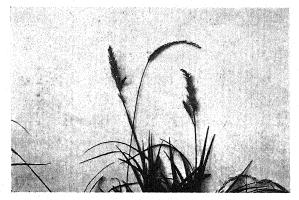

Fig. 20. Female inflorescences, one unbranched and two with lateral shoots at their bases.

Variations in the axes of the florets of *Carex* are frequently cited in the general literature on the genus, and the inflorescences of this dioecious species show variations which may be used to establish interesting correlations.

The pistillate spikelets thus far discussed have all been alike in possessing the morphological essentials of fertility (fig. 13). Whether or not fruits are ultimately formed is irrelevant. Besides these, there are spikelets with imperfectly formed flowers at the tips of inflorescences and sterile ones scattered among the fertile. Each of the latter, like the normal pistillate spikelet, has a short lateral axis of limited growth and is enclosed within a bracteole; the difference is that a gynoecium does not develop. A cross-section taken near the base of such a spikelet shows its axis encircled by the perigynium, but no trace of a pistillate flower is discernible (fig. 14). The fertile spikelets are numerous and prominent; the sterile are few in number, inconspicuous, and confined largely to the base of the inflorescence. A natural supposition is that the sterile spikelet is a modification of the pistillate in which the primordium of the pistillate flower has aborted.

Some other modifications, although less common, are equally interesting. It has been emphasized

that the axis of the pistillate spikelet aborts beyond the attachment of the flower. In C. picta the aborted tip is in most instances no longer than the stipe of the ovary (fig. 15). That this aborted terminus varies in length and function within a species of Carex has been known for some time. In 1873 Townsend made several general statements on its variable nature, calling it a seta. Two years later Eichler substantiated previous observations on the variability in the axis of the spikelet of C. microglochin, which had been described as often projecting above the perigynium and, under special treatment, even producing staminate flowers. More recently, abnormal pistillate spikelets with fertile stamens have been described for species of Carex, and rudiments of male florets have been observed along the tips of the axes of pistillate florets of some species.

In the study of serial sections of numerous spikelets of Carex picta, several interesting variations were found in the axes of the florets. Nothing comparable to a bisexual spikelet was found, but considerable variation in the length of the axes is apparent (fig. 15, 16, 17, 18). The spikelets were removed from the rachis and sectioned individually, and it was learned that when one spikelet of a specific inflorescence was found with an unusually long rachilla, the same would be true of many of the remaining ones. Whether or not this peculiarity was confined to a single inflorescence, or was characteristic of all the inflorescences of a given plant, was not determined. The longest axes observed (fig. 18) were almost twice the height of the developing

fruit.

Many of these axes, regardless of their length, exhibited a characteristically contracted terminal portion, which suggested that the aborted end had started to develop and then died and shriveled. An especially long terminus of this nature is illustrated in a spikelet with an axis of intermediate length (fig. 16). In most instances this rudiment apparently ceases to develop at about the time of the maturity of the embryo sac (fig. 15, 19).

Even more pronounced variations in the pistillate shoot have also been observed. Secondary branches, bearing spikelets like those on the main, usually unbranched axis, are sometimes found in the axils of bracts near the bases of inflorescences (fig. 20), but they are not at all as frequent as those variations detected with the microscope. Only five were observed, and four grew on plants in the greenhouse, three of the latter developing as a secondary growth in inflorescences far past their normal flowering period, and the other as the stigmas of the flowers of the main axis began to die. All of the components of the one branched inflorescence found in the natural habitat were formed at approximately the same time.

These lateral shoots were found to have characteristics in common with the pistillate spikelets. The base of each was surrounded by a bracteole (fig. 21), and each arose from the axil of a bract

similar to that which subtended the spikelets. If the lateral shoots were permitted to remain attached until fruits matured, the entire shoot fell from the inflorescence, a characteristic common to individual spikelets. The conclusion naturally follows that these long branches have developed from the axes of spikelets which did not abort in the usual manner.

The variable character of the bracteoles enveloping the basal portions of the long branches deserves additional comment. In the case of the secondgrowth branches which developed in the greenhouse, the bracteoles were of the normal bidentate form, while on the one branch which developed simultaneously with the fertile spikelets, out of doors, the bracteole was split down the abaxial side. That is, the bracteole, having played the rôle of a perigynium previous to the development of the branch, still portrays the bidentate character, while that which developed simultaneously with its axis was split down the abaxial side. The open bracteole is more like the typical monocotylous prophyll, while the closed ones substantiate clearly the assumption that the axis of a spikelet is in reality an aborted floral branch. The variations in these bracteoles provide good additional evidence as to the probable ontogeny and phylogeny of the perigynium.

The staminate floral unit, because of its simplicity, has always been considered self-explanatory, and the many discussions on Carex florets have centered around the pistillate unit. Classification of the perigynium as a specific type of floral component and then determining it as a simple or compound structure have been interesting and significant subjects for discussion and investigation; in the end they have disclosed the morphological nature of the floret. On the other hand, the staminate unit has received less attention, probably because it is thought to be easily understood. This apparent simplicity may, however, obscure an intangible complexity.

A clue to the morphological nature of this floral unit is found in an abnormal staminate floret of Carex acuta L. mentioned by Boott (Holm, 1896). This floret, as illustrated, has the stamens enclosed in a perigynium. The perigynium, as associated with the pistillate floret, necessitates the presence of a rachilla. As has been stated, neither a secondary axis nor a bracteole is associated with a typical staminate floret, and their existence in this instance suggests that, phylogenetically speaking, they might have been present in a previous form. We may assume, then, that the male spikelet as it exists is now highly specialized, the bracteole and its axis having been reduced to mere potentialities, and the three characteristic stamens arising from the hypothetical axis.

To test this assumption, a study has been made of the ontogeny and variations in the male floret. Serial sections have been made of spikelets of all ages from the time of the appearance of the first primordia to the full development of the typical

components. In the embryonic male flower bud collected during August, the beginnings of the staminate spikelet, a bract primordium and an axillary axis, are in evidence at the tip of the inflorescence. The former is short, rounded, and ridgelike, the latter hemispherical. Both appear like the two initial primordia of the female inflorescence. Each develops rapidly, the bract primordium soon covering the axillary. From the latter, three

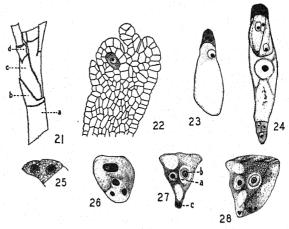

Fig. 21–28.—Fig. 21. Junction of lateral shoot and ma'n axis a, scape; b, subtending bract partly cut away to show bracteole; c, bracteole; d, axis of secondary shoot.—Fig. 22. slightly adaxial terminal lobes appear when the primordium has become scarcely longer than broad. These lobes mature rapidly into three stamens, and their basal beginning becomes scarcely perceptible.

The initial stages in the development of the staminate spikelet add little support to the assumption that this floral unit once possessed the constituents of the pistillate floret. The similarity of the first two primordia of both spikelets might be considered favorable evidence, but little emphasis should be placed upon it, since the sequence of these primordia is typical for leaves and axillary axes in general. In this the observation, however, does support the idea of the development of the stamens of the male flower from a rudimentary rachilla rather than directly from the rachis of the inflorescence. Their apparently adaxial development is of problematic importance.

Additional support favoring the development of the staminate flowers from a secondary aborted axis is found in the occurrence of typical pistillate florets at the base of a staminate inflorescence. Such a condition is abnormal for the species, but it is significant because a female floret has developed in a position normally occupied by a male. It has been definitely ascertained that the female flower develops from a secondary axis, and it is probable that the same holds true for the male. The development of a more elaborate floral unit in the position of one with fewer components makes it appear as if the two may have a common origin. This is in agreement with ontogenetic observations of the two units. It follows, then, that when a pistillate floret replaces a staminate one, the primordium of the floret undergoes a transition which Schaffner has called a change of "functional activity." In the one instance, a condition prevails which limits the development of the secondary floral axis to the production of a single flower, three stamens, before it aborts; in the other, a condition occurs which promotes the development of a flower and its subtending bract, the perigynium, on an axis which is plainly evident beyond the place where the flower

In the literature it is suggested that the pistillate flowers of Carex develop upon secondary axes, the staminate on the primary axis. The evidence furnished by a comparative study of the development and variations of the pistillate and staminate florets of C. picta suggests that the two kinds of florets represent axes of the same rank which differ in their degrees of development. Either type of axis is easily overlooked in floral analysis. That of the pistillate floret is the more easily recognized, but may require a microscope. The rachilla of the male floret is poorly developed and is detected only during early stages of development. It is not unusual for the axis of the female unit to vary in length, and these variations clarify its identity. Variations were not observed in the axes of male florets, and, when an axis on which a male flower is expected to develop becomes longer than is typical for the staminate unit, it apparently changes its functional activity, and a pistillate flower is produced.

Gametogenesis.—In connection with the study of floral expression and floral development, the following observations were made on gametogenesis. The development of both gametophytes is much the same as Heilborn (1918) has described for some other species of Carex. Since no dioecious species were included in his discussion, however, and since there appear to be some slight differences between Carex picta and the vernal species with which he dealt, descriptions of male and female gametophytes are of interest.

The observations on megagametogenesis were made from slides prepared for studying the ontogeny of the female spikelet. Several fixing reagents and staining combinations were used with success, and the sections were cut at various thicknesses ranging from 5 to 15 microns.

Normally a solitary cauline ovule arises in the bottom of the one-celled ovary, and, before differentiation takes place, the ovule primordium stands as a straight, short-cylindrical organ (fig. 10, d). As a centrally located hypodermal cell, the archesporial cell, enlarges and divides anticlinally forming a parietal cell and a megaspore mother cell, the ovule begins to bend toward the rachis, and the inner integument appears.

This differentiation, in Carex picta, takes place in the fall, while in those vernal species investigated by Heilborn (1918), the archesporial cell did not develop until the following spring. female spore mother cell in C. picta, which is often differentiated in September, enlarges slowly, but does not undergo division until a few days before The parietal cell soon divides perianthesis. clinally, and the initial of the outer integument becomes apparent in a short time (fig. 22); but other changes in the ovule follow slowly. As the bending ovule gradually turns over, the integuments form a double jacket of tissue over the nucellus, and the cells adjoining the megaspore mother cell undergo a few divisions. The tissue between the megaspore mother cell and the epidermis, however, seldom becomes more than two cells in thickness before maturation. This is another exception to what Heilborn found. He described the spore mother cells as becoming more deeply embedded, and the same is shown in illustrations by Wahl.

Frequently, as is characteristic of anatropus ovules, the outer integument fails to develop on the side of the ovule which is being folded back upon the funiculus, and this folding may also affect the uniform development of nucellar tissue, growth being suppressed adjacent to the region where the ovule pushes against the ovary wall. Usually during March of the following year, the ovule rapidly increases in size, and the "normal-type" of embryo sac (Schnarf, 1936) develops from the megaspore mother cell within a few days. The details of the formation of the linear tetrad from the mother cell were not observed, but that the chalazal megaspore is the one to germinate is definitely indicated in sections of the ovule made at any time between the first steps in the germination of the megaspore and the maturity of the embryo sac (fig. 23, 24).

It has been known for some time that, as a rule, in *Carex* only one pollen grain develops from a microspore mother cell, but it was considered worth while to investigate this point in a dioecious species. Both serial sections and permanent smears were used in this part of the study.

Cross-sections of anthers show no unusual features. The slender, deeply four-lobed anthers dehisce along two collateral sutures, the pollen developing in four long, slender, cylindrical sporangia. The sporogenous tissue is differentiated in

<sup>3</sup> Illustrations on megasporogenesis (Hill, Overholts, and Popp).

September and October, but the microspore mother cells (fig. 25) do not undergo division until immediately preceding anthesis; so rapid is the formation of pollen from the mother cells that the stamens of one floret of an inflorescence may contain mature pollen while the fertile tissue of an adjoining one is still in the spore mother cell stage.

The nucleus of the mother cell usually gives rise to four nuclei4 (fig. 26), but in some instances one or two additional divisions occur so that more than four nuclei are formed. However, in most cases observed, all except one of these remained at the bottom of the cuneate mother cell. After short time the latter disintegrate and become very inconspicuous. The persisting nucleus migrates toward the center of the cell and typically divides immediately to produce a tube cell and generative cell (fig. 27, 28). In the usual form of microsporogenesis four spores are developed from a mother cell, and an equal number of pollen grains are produced. Species of Carex then produce only one-fourth as much pollen, in proportion to the number of microspore mother cells present, as is formed by most plants.

Pollen grains germinated on a solution of 2.5 per cent cane sugar and 1 per cent agar produced tubes from lateral germ pores and from the large end of the grain (fig. 29, 30, 31). In a few instances two tubes grew from a pollen grain (fig. 31). This was of more than usual interest, as the germination of the persisting microspore was at times followed with difficulty (fig. 32, 33) and in a few cases it appeared as if two tube nuclei and two generative cells had developed in a pollen grain. It is likely that grains of this nature are the ones to develop more than one pollen tube.

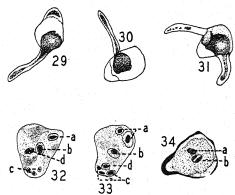

Fig. 29-34. Germinating pollen grains.—Fig. 29. Pollen tube coming from enlarged end of pollen grain.—Fig. 30. Pollen tube coming from side of pollen grain.—Fig. 31. Two pollen tubes from one pollen grain.—Fig. 32-33. Pollen grains with more than typical number of cells; a, tube nucleus; b, generative cell; c, disintegrated "microspores"; d, probable second generative cell having divided in figure 32.—Fig. 34. Normal pollen grain; a, tube nucleus; b, generative cell having divided; and remnants of disintegrating "spores" not perceptible.

\* In some instances these nuclei appeared to develop a wall, while in others they did not.

The generative cell was observed to divide before the pollen tube developed (fig. 34), but the nature of this division, and the behavior of the male gametes and tube nucleus in the pollen tube have not been worked out. Fertilization was not observed, but pollen tubes were found to reach the ovule 8 to 12 hours after pollination. Plants are often ready for pollination by the middle of March in our latitude, a time subject to radical changes in temperature, and there may be considerable differences in the length of the interval required for the pollen tube to complete its growth.

Incidentally, chromosomes were observed in microsporogenesis of one flower. Counts were made from longitudinal serial sections cut 10 microns thick and stained with the crystal violet chromosome stain. Most of the pollen mother cells in each of the three anthers were undergoing maturation. The chromosomes studied were in the metaphase of the first division; and, from ten cells suitably oriented, the zygotic number seems to be 32.

### SUMMARY

Floral analyses show that the sexual expression in Carex picta is remarkably uniform, and the occurrence of an occasional androgynous inflorescence corresponds to a condition known for other species described as dioecious.

The sequence of the primordia in the development of the pistillate inflorescence shows that the pistillate "flower" of this species is actually a floral unit, and the true female flower in the form of an unattended pistil is attached to a rudimentary rachilla, both pistil and rachilla being surrounded by a bracteole. This interpretation is not new for species of Carex; but it has heretofore been based upon other evidence.

Variations in the length of the female floret axis occur in Carex picta, as have been found for other Carices. A part of these variations of the rachilla exist within the perigynium, but a lateral shoot resembling the usual solitary inflorescence may develop from the rachilla of a basal spikelet. These variations also aid in explaining the morphological nature of the female floret.

The apparently self-explanatory staminate floral unit also develops upon a secondary rudimentary axis and seems homologous to the pistillate, its apparent simplicity being due to its highly evolved nature.

In megasporogenesis a hypodermal archesporial cell is differentiated and divides, giving rise to a megaspore mother cell early in the autumn preceding anthesis. According to the literature, in other vernal species this differentiation does not take place until the following spring.

Nucellar tissue before maturation is not as abundant as has been found in the ovules of other Carices; however, the anatropous ovule and the development of the common type seven-celled embryo

sac from the chalazal megaspore agrees with descriptions for other species.

Microsporogenesis is typical for most sedges, but it is unusual for flowering plants in general in that only one of the "spores" resulting from maturation develops into a pollen grain. It is also unusual to have the wall of the spore mother cell become the wall of the pollen grain.

The generative cell was found to divide before a pollen tube developed. Pollen tubes usually reach the embryo sac within 12 hours after pollinaPollen tubes grow from the broad end or from the sides of the cuneate pollen grain.

In some instances two pollen tubes grow from a single pollen grain, and the occasional presence of more than two apparently functional cells in developing pollen grains is logically associated with the development of two pollen tubes from one grain.

The zygotic number of chromosomes seems to be 32.

## SOME PHYSIOLOGICAL CHARACTERISTICS OF MYXOMYCETE SWARM-CELLS 1

## Paul E. Kambly

Since Harper (1900) discussed nuclear fusion in Fuligo septica and Pinoy (1908) postulated + and — amoebae of Didymium nigripes there have been several studies of "sexual" phenomena in the life histories of Myxomycetes. Most of these studies have been concerned with the interpretation of nuclear changes. Monoploid and diploid phases have been discussed by Jahn (1911, 1936), Skupienski (1927), Wilson and Cadman (1928), Cayley (1929), Schünemann (1930), Howard (1931) and von Stosch (1935, 1937). In contrast with these papers on nuclear phenomena in the life histories of Myxomycetes, Abe (1934) made a study of certain physiological characteristics of Myxomycete swarm-cells, using Fuligo septica, Erionema

<sup>1</sup> Received for publication October 31, 1938.

The writer wishes to acknowledge his indebtedness to Prof. G. W. Martin for helpful suggestions during the progress of the work and to express his appreciation to Prof. W. F. Loehwing and Dr. T. L. Jahn, who, by their advice and criticism, have aided in the development of this presentation.

aureum, Didymium nigripes, Physarum crateriforme and Stemonitis fusca. She found that there was a fusion of swarm-cells in all these species. She observed accompanying karyogamy in Fuligo septica and Erionema aureum. Since in every case the fusing cells were isogamous, she called the cell which "flowed" into the other the "male." Beginning with this assumption of "male" and "female" swarm cells, she performed a series of physiological experiments designed to discover differences in these two lines. On the basis of the reactions of swarm-cells to indicators and other chemical compounds, she concluded that there is no difference in their pH; that the "male" has a higher oxidationreduction potential than the "female"; and that the "female" has a positive electrical charge and the "male" a negative charge.

A review of the literature reveals that no other work of similar nature has been reported for the swarm-cells of Myxomycetes. Since the clear-cut differences which Abe describes between the members of a fusing pair of swarm-cells would be of considerable significance in explaining the phenomena of sex in lower organisms an attempt was made to substantiate her findings. This paper is a report of a series of experiments designed to study the pH, the reducing intensity, the surface charges of swarm-cells, and the effects of vital stains and toxic ions on them.

MATERIALS AND METHODS.—Reticularia Lycoperdon was chosen for study because 85-95 per cent of the spores germinate in distilled water in less than an hour and because the details of its cytology have been reported by Wilson and Cadman. The protoplast which emerges from a Reticularia spore soon develops its swarm-cell characteristics and retains these characteristics until fusion. Very often these swarm-cell characteristics are observed in the zygote. Except in a few late checks, all Reticularia spores used were from a collection made at Iowa City on September 10, 1934. The swarmcells of Enteridium Rozeanum (coll. Nov. 18. 1934), Stemonitis Webberi (coll. July 28, 1934), and Fuligo septica (coll. June 27, 1936) were used at different stages in the study to check the results obtained with Reticularia.

All spores used in these experiments were germinated in ordinary distilled water in Syracuse watch glasses at room temperatures varying from 20°C. to 27°C. The pH of this water changed with ageing cultures so that in three days it was approximately 5.2. When the effects of dyes or indicators were studied, a drop of the culture was transferred to a depression slide and a small amount of the reagent added. Observations were made with a 10× objective and a 3 mm. Spencer water immersion lens. A Bausch and Lomb substage lamp furnished the source of light. Special methods and materials used in specific experiments will be described in connection with the discussion of these experiments.

EFFECTS OF CERTAIN VITAL STAINS.—Since Wilson and Cadman had reported that a number of mitotic divisions took place before swarm-cells were able to fuse, it seemed possible that the mitotic divisions were accompanied by physiological changes which resulted in the ability to fuse. For this reason the effect of vital stains on the swarm-cells taken from cultures of varying ages were studied.

Methylene blue, neutral violet, neutral red and Janus green were used in 0.01 per cent aqueous solution. The results obtained were not consistent. If the swarm-cells were left in the stain long enough, it was usually possible to make observations at a time when approximately 50 per cent were unstained. The heavily stained cells were granular in appearance and probably dead. If the concentration of the stain was lowered to the point where the swarm-cells would remain active, no difference in staining reaction was evident. In every case where fusing cells were observed, both members remained unstained at least as long as they

were active. In one instance a drop taken from a 36 hour culture was placed in 0.1 per cent methylene blue and three fusing pairs were observed. All three pairs remained colorless while many spherical cysts in the same field became intensely blue. Very often the stains caused the spherical swarm-cells or zygotes to swell and finally to burst. The more fluid portion of the cytoplasm flowed out through the ruptured cell-membrane leaving the stained granules behind. This produced what appeared to be two connected cells one of which was heavily stained and the other unstained.

Abe reported that swarm-cells killed in osmic acid vapor and then placed in the dyes showed a differential stain similar to that which she obtained with living cells. This result was confirmed but the question arises as to whether this difference in staining reaction is due to physiological activities which cease with death of the cell or whether these differences could be explained on other grounds. Further tests, in part similar to Abe's, were made, therefore, in an attempt to discover whether there were not other factors which would aid in explaining the presence of stained and unstained swarm-cells in the cases where it did occur as described in the above paragraph.

PH of swarm-cells.—Small's (1929) range indicator method of studying pH was used. With one exception indicators in both 10 per cent alcohol and in aqueous solution were made up in concentrations of 0.01 to 0.04 per cent. Di-ethyl red was made up only from an aqueous solution. The swarm-cells were left in the indicators until a uniform color was evident, the time varying from a few minutes to ten hours. Motility of flagellated swarm-cells is an obvious evidence of life. In most of the tests the flagella were retracted and cysts formed before any color was visible, so that it is probable that the color reactions obtained were in dead cells. This raises the question as to how much the pH of the cell contents changes on death.

In discussing this method of determining pH Small says, "The many times repeated tests had shown that there were no color differences between alcoholic and aqueous indicators, and that there were no color differences between periods of immersion of one hour to twenty-four hours. . . . It, therefore, appears reasonably certain that the observations made quickly are, in most cases, made upon living cells, while the later observations are made upon dead cells. The comparative tests indicate that the later observations can as a rule be taken as giving the initial pH of the living cells when the R. I. M. is used. With 'tint' indicator methods the results would be too complicated by this factor to be at all reliable." If Small's findings on the cells of higher plants are applicable to swarm-cells, then the results shown in table 1 are valid.

Except in the tests with methyl and di-ethyl red the colors obtained were very evident. The swarmcells appeared very faintly yellow in these two

Table 1. pH value of swarm-cells.

Indicator	Conc.	Alk. color range	pН	Acid color range	pН	Color of swarm- cells
Brom-thymol blue						
(Dibromothymolsulfonphthalein)	0.04	Blue	7.6	Yellow	6.0	Yellow
Brom-cresol purple						
(Dibromo-o-cresolsulfonphthalein)	0.04	Purple	6.8	Yellow	5.2	Yellow
Di-ethyl red						
(o-carboxybenzene-azo-diethyl-aniline)	0.04	Yellow	5.9	Red	5.6	Yellow
Methyl red						
(o-carboxybenzene-azo-dimethyl-aniline)	0.03	Yellow	5.6	Red	5.2	Yellow
Benzene-azo-a-naphthylamine	0.01	Yellow	4.8	Red	4.4	Yellow
Brom-cresol green						
(Tetrabromo-m. cresolsulfonphthalein)	0.04	Blue	4.4	Yellow	4.0	Blue

indicators. Benzene-azo-a naphthylamine was the only indicator which gave an immediate uniform color reaction in the swarm-cells. It should be pointed out that when using brom-thymol blue, brom-cresol purple and brom-cresol green, it was possible to make observations at a time when the swarm-cells were not uniformly colored and on the basis of those observations conclude that the pH of the cells differed. When they were left in the indicators as advocated by Small, a uniform coloration resulted which indicated a pH of approximately 6.

REDUCING INTENSITY OF SWARM-CELLS.—Table 2 shows the results obtained with a series of oxidation-reduction indicators. All the indicators were used in studying suspensions of *Reticularia* swarm-cells. They were added to 2 cc. of suspension in distilled water to make approximately a M/10,000 concentration in each vial. The effect of the indicators on the color of the swarm-cells was determined by observation with the water immersion lens. The tests were made at room temperatures varying from 22°C. to 26°C.

Table 2. Results with oxidation-reduction indicators.

Indicator	Color of swarm-cells in indicator	Effect of suspension on indicator
Phenol indophenol	Colorless	Reduced
0—cresol indophenol 1—naphthol—2—	Colorless	Reduced
sulfonate indophenol	Colorless	Reduced
Brilliant cresyl blue	Colorless	Reduced
Gallocyanin	Colorless	Reduced
Methylene blue Indigo tetrasulfonate Methyl capri blue nitrate	Some blue Some colorless Colorless Colorless	Not reduced Not reduced Not reduced
Indigo trisulfonate	Colorless	Not reduced
Indigo disulfonate	Colorless	Not reduced
Indigo monosulfonate	Colorless	Not reduced
Phenosafranine	Red	Not reduced
Neutral red	Some red Some colorless	Not reduced

On the basis of the results given in table 2, methylene blue and neutral red are the only indicators which give any evidence of two "lines" of swarmcells. In order to recheck this phenomenon of differential staining in methylene blue, a solution of LaMotte special methylene blue was used. In a M/10,000 solution of this indicator occasional blue quiescent swarm-cells appeared within ten minutes, and if left several hours practically all became blue. If the swarm-cells were first killed in osmic acid vapor and then placed in the indicator, they became uniformly blue within ten minutes. If this special methylene blue failed to stain the majority of swarm-cells because of their reducing intensity, then killing the cells in osmic acid vapor should result in their staining blue upon being placed in the indicator. Since this was the result obtained, the question arises as to whether those swarm-cells which were quickly stained blue in living cultures became colored because of a difference in reducing intensity or because they were dead. The latter seems to be the obvious answer.

Hewitt (1931) lists the errors involved in the use of oxidation-reduction indicators as follows: "(1) Damage to the cell by the dye or by injection. Although the cell may survive, the injury may have altered the electrode potential. Either the oxidised or reduced form of the dye, or both, may be toxic. (2) The dye may catalyse biological oxidations (or act as oxygen carrier) and hence alter equilibrium. (3) The capacity of the dye system may be so large, compared with the biological system, that equilibrium may be disturbed, and the time involved for the reattainment of equilibrium may be very long. (4) The properties of the dye may be altered by combination with cellular contents, etc."

The chief object in studying the reducing intensity was to determine whether swarm-cells differed in this respect as stated by Abe. Since this did not involve an accurate quantitative determination, some of the sources of error listed above need not be considered. Since the results obtained indicate a uniform reducing intensity, they are not in accord with Abe's conclusion.

Effects of toxic ions on swarm-cells.—In discussing this topic Abe wrote, "If gametes are negatively charged, they must absorb cathion, and if positively charged, anion. In order to see whether the gametes show any difference in resistance against toxic ions or not, the writer [Abe] tested the action of CuSO<sub>4</sub> and KCN at several concentrations. In 0.03 mol solution of CuSO<sub>4</sub>, half of the gametes of Fuligo septica and Didymium nigripes at once coagulated and sank to the bottom, while the other half continued the movement for a few minutes. The gametes were separated into two parts by sucking up the upper part of the gametes with a pipette. By adding 0.01 per cent solution of neutral red or methylene blue to each of these two portions, the coagulated gametes were stained red or blue, while the other gametes became vellowish. In 0.03 mol solution of KCN for ten minutes some of the gametes stopped the movement and become spherical, while the others continued the movement in the comma-shaped form. Gametes are fixed in such a state in the vapour of osmic acid for 30 seconds. Staining them with a very weak solution of methylene blue we find that the comma-shaped gamete appears blue, while the spherical gametes appear yellowish blue. We may come to the conclusion that the male gamete is less resistant against CuSO4 than the female, and vice versa against KCN. In other words, the cathion (Cu<sup>++</sup>) acted on the male gamete, and the anion (CN-) on the female gamete, so that it may be said that the male gamete is negatively charged and the female gamete is positively charged.'

M/300 copper sulphate killed some swarm-cells more quickly than it did others. Those which rounded up first settled to the bottom of the watch glass and could be removed with a pipette. These coagulated cells became blue when placed in 0.01 per cent methylene blue much more rapidly than those which were still active. This is in accord with Abe's findings.

Abe's results with potassium cyanide could not be repeated. Swarm-cells left in M/300 potassium cyanide and then killed in osmic acid vapor became uniformly blue in dilute methylene blue.

The fact that the swarm-cells which died first when placed in M/800 copper sulphate became blue when placed in 0.01 per cent methylene blue was not surprising, because they had the same coarse granular appearance of the stained cells discussed under vital staining. If a group of organisms placed in an unfavorable environment is observed at the proper time, it will be evident that approximately 50 per cent are affected by the change in environment and 50 per cent are unaffected.

If conclusions concerning the electrical charge borne by swarm-cells are to be drawn from experimental work with toxic compounds such as copper sulphate and potassium cyanide, it will be necessary to demonstrate a relationship between electrical charge and toxicity. KCN may be toxic by virtue of the undissociated HCN molecules which penetrate the cell, rather than by its CN-ion. It seems fallacious to conclude that organisms which are first affected by these toxic compounds are affected because they bear a different charge than similar organisms which are able to withstand the toxic effects for a slightly longer period.

Surface charge of swarm-cells.—Abe's conclusions concerning electrical charge were based in part upon experiments with potassium ferrocyanide and iron chloride. She placed swarm-cells in 10 per cent solution of potassium ferrocyanide on a glass slide and evaporated the fluid over a flame. After washing with water, a 10 per cent solution of iron chloride was added to the slide. She states that, "Some of the gametes were stained greenish blue, while others remained unstained, so that the former is considered to be female, having positive charge, and the latter male, having negative charge."

When swarm-cells were placed in 10 per cent potassium ferrocyanide on a glass slide and the solution evaporated over a flame, the cells shrunk excessively and were difficult to distinguish in the mass of crystals. When 10 per cent iron chloride was added, it was impossible to distinguish two lines of differently stained swarm-cells as described by Abe. Using the same solutions and centrifuging the swarm-cells through the potassium ferrocyanide and water also yielded poor results because of the shrinking of the swarm-cells. There were some spherical forms but none were present which were blue in color. It was found that when the concentration of the potassium ferrocyanide was lowered to 5 per cent the swarm-cells rounded up but did not shrink. These cells were washed through several changes of distilled water by centrifuging and then removed with a pipette and added to 10 per cent iron chloride. These were observed with the water immersion lens and were uniformly lightly stained. This was true of swarm-cells taken from cultures of varying ages.

These results did not substantiate Abe's findings. Lowering the concentration of the potassium ferrocyanide should not inhibit the adsorption or entrance of the Fe(CN)<sub>6</sub> ions into swarm-cells if the entrance is due to the electrical charge as she postulated. Since a uniform pale blue to colorless reaction was obtained with the lowered concentration, it is doubtful if her interpretation was correct. Her results suggest that the swarm-cells subjected to the extremely toxic concentration were affected in different degrees and because of greater or less entrance of ions showed a difference in intensity of staining. This is exactly what one would expect if observations were made at the proper stage of the experiment.

The electrical charge borne by the swarm-cells within the pH range of the distilled water used in

these experiments was determined by observing their electrophoretic movements. An electrophoretic cell was built by cementing two glass slides to a flat glass plate. The ends of this cell were sealed with agar. The electrodes used consisted of glass tubes with flared and flattened ends plugged with agar which was prepared with distilled water. A concentrated zinc-sulfate solution was placed in the tubes and zinc strips were immersed in the solution. The agar plugs in the flared ends of the electrodes made contact with the agar ends of the cell. The agar parts were freshly made each time the cell and electrodes were used. Dry cells were used as a source of potential.

When a suspension of swarm-cells was placed in this cell, it was sealed over with a coverglass and vaseline. In a field with a potential drop of approximately one volt per centimeter the swarmcells, cysts and zygotes moved uniformly toward the positive electrode. When the current was reversed, the direction of migration was immediately reversed. This was true of swarm-cells of various ages. In no case was there migration of all or part of the cells toward the negative electrode at any level in the cell.

Since migration in an electrical field is due to surface charges and these charges may have nothing to do with staining reaction, no definite conclusions concerning staining reaction can be drawn from the described mass migration toward the anode. The uniform migration does indicate that if swarmcells react to vital stains differently because of opposite electrical charges the presence of these charges cannot be detected by the method described.

#### SUMMARY

The swarm-cells of Reticularia Lycoperdon were studied in an effort to discover physiological factors which are associated with the ability to copulate. This paper is a report of experiments to determine the pH, the reducing intensity, the surface charges of swarm-cells, and the effects of vital stains and toxic ions on them.

When placed in certain vital stains, all swarmcells did not stain uniformly or at the same rate. Very often there were many heavily stained cysts and cysts which were not stained.

As determined by Small's range indicator method, the pH of the swarm-cells was found to be approximately 6.

Oxidation-reduction indicators revealed no definite difference in reducing intensity between swarmcells of the same age or of different ages.

Experiments with copper sulphate, potassium cyanide, potassium ferrocyanide, and iron chloride did not support the view that there are oppositely charged swarm-cells which copulate partly because of an opposite electrical charge.

Using an electrophoretic cell, the surface charge borne by swarm-cells, cysts, and zygotes was found to be negative. There was no evidence of positively charged swarm-cells at any age or at different levels of the cell.

The difference in staining reaction in vital stains was probably not due either to a difference in reducing intensity or electric charges as postulated by Abe.

## THE MORPHOLOGY AND EMBRYOGENY OF SEQUOIA GIGANTEA <sup>1</sup>

J. T. Buchholz

WHEN ONE considers the difficulties encountered in collecting material for a study of Sequoia gigantea, he comes to appreciate one of the reasons why this species has been neglected by morphologists. In cultivation at lower altitudes the ovules and seeds of the cones that may occasionally be found are usually abortive. In the mountainous region of the Sierras where this species is native and reproductive, the trees are so large that one cannot hope to obtain cones from them without expensive equipment and preparation. The fact that the cones persist on the trees for many years after the seeds are mature (Buchholz, 1937, 1938a) has not been generally understood and adds to the difficulties confronting the collector. To be sure, squirrels often cut off cones which may be picked up under the trees, but these are usually the older ones. Various individuals have collected and sent me cones at different times during the past twenty years. cones received were found to be fully matured.

During the spring and summer of 1936 the writer went to California for the purpose of making a study of the Sequoias. The only practical plan worked out at that time which would not entail expensive equipment was to use the occasional cones produced on the small second-growth trees. Trees less than 75 years old are abundant in Whitaker Forest, a preserve owned by the University of California near Redwood Canyon. They are also abundant in the cut-over region near General Grant National Park.

During late June and early July while the new cones are still only partially grown, they may be recognized with field glasses by their smaller size and lighter color. It was found (Buchholz, 1938a) that while only one tree in several hundred in this second-growth stand may bear one or two cones (always near its top), they may be marked and mapped for collections during the summer when the cones are in the desired stage. About eight such trees were found, and the cones collected from them furnished me with the material for a study of the

embryogeny.

The stage of fertilization was not included. The cone collected nearest that date happened to be a teratologically misshapen specimen containing very few normal ovules. Some of the other collections were spaced a little too far apart in time, but the cones obtained were excellent and yielded an abundance of embryological material in their respective stages both before and after fertilization.

It was very fortunate and timely for my work that Looby and Doyle (1937) recently published their account of fertilization and the proembryo from material obtained in cultivation in Ireland. Had the writer planned a cooperative research with these investigators so as to pool all efforts in a study of the embryogeny of the big tree, a more

<sup>1</sup> Received for publication December 12, 1938.

precise division of labor could not have been outlined. Their account has supplied the stages missed by the author and enables him to describe the embryogeny with a satisfactory understanding of the proembryonic stages.

It is of great importance to know that the proembryo of Sequoia gigantea has a free nuclear stage and to know how this proembryo is organized. The younger stages observed by me and shown in figures 23-25 represent the stage in which Looby and Doyle left off in their account. Thus, it is now possible to give a fairly complete general outline of the early embryogeny of this species.

The ovules were collected and killed in Nawaschin's solution and in formalin-acetic-alcohol. The latter killing solution was found more satisfactory on the whole. Some of the material was cut serially in paraffin and stained by the usual methods. Nearly all the material that was ultimately found useful in a study of the later embryo was dissected material, the preparation of which has been described in considerable detail elsewhere (Buchholz, 1938b). For the last stages before fertilization and all subsequent stages, the seed coats must be removed; otherwise the seeds cannot be cut, because there is hardened tannin jell in the cells. The nucellus is thin and may be cut in paraffin without difficulty. Sections were cut in longitudinal axis and transversely. The most satisfactory orientations for cutting were those giving transverse serial sections of the nucellus.

The literature on the morphology of Sequoia gigantea is very meager. Strasburger (1872, 1879) described the cones of S. sempervirens, confining himself very largely to external morphological features and the vascular supply of the cone scale. Arnoldi's account (1900) is the only earlier one which gives anything specific on the internal morphology of the Big Tree. His studies were made from material found in cultivation in the old world and do not include the embryo. The accounts of Shaw (1896) and Lawson (1904) were confined to S. sempervirens. Looby and Doyle's investigation covering fertilization and the proembryo is the first and only investigation of the Big Tree which includes a detailed account of these stages.

In the following account of the gametophytes I am adding some new observations and repeating here and there a number of features covered by previous investigators. This duplication appears necessary in using my figures in the presentation.

Figure 1 is a drawing showing the upper surface of a cone scale just before pollination. At this time the ovules are still very small and immature, consisting only of a nucellus bordered by the integument, which is merely a narrow rim. They may be described as appearing erect at this stage. With the enlargement of the cone scale after pollination, the ovules grow rapidly and soon develop to the

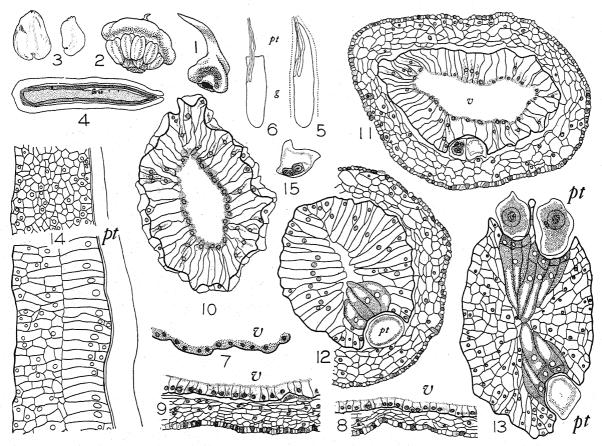

Fig. 1-15.—Fig. 1. Ovulate cone scale of Sequoia gigantea viewed from above, before pollination. Ovules are borne in two crescentic rows. X5.—Fig. 2. Ovulate cone scale of Sequoia gigantea from a cone two-thirds grown, showing two rows of ovules.—Fig. 3. Ovules showing winged margins and variations in shape—placed with micropyles pointing upward.—Fig. 4. Section of ovule showing micropyle at right and nucellus (shaded) containing female gametophyte beside pollen tube shortly before fertilization. ×6.—Fig. 5. Male and female gametophytes removed after fertilization showing lateral position of pollen tubes; dotted line = boundary of nucellus before removal. ×6.— Fig. 6. Same, with upper portion of female gametophyte removed by dissection.—Fig. 7. Part of megaspore membrane showing cytoplasm and nuclei surrounding large central vacuole (v) in free-nuclear stage of female gametophyte. July 14, 1936. ×100.—Fig. 8. Portion of wall of nucellus from transverse section through upper portion of female gametophyte showing beginning of wall formation between nuclei which are still lying close to megaspore membrane; v, position of large central vacuole.—Fig. 9. Same as fig. 8 through lower portion of same nucellus and female gametophyte. July 17, 1936. ×100.—Fig. 10. Transverse section through female gametophyte at level below ends of pollen tubes, showing later stage in wall formation, the nuclei and cytoplasmic layer having moved opposite the newest part of cell wall. July 17, 1936. ×100.—Fig. 11. Same as fig. 10 but including nucellus, through lower portion of pollen tubes. Two pollen tubes are shown between nucellus and megaspore membrane imbedded in a groove of female gametophyte. The pollen tube at the left shows body cell slightly enlarged beside stalk and tube nucleus; v, central vacuole. ×100.—Fig. 12. Slightly later stage than fig. 10 and 11, with cells meeting at center and closed, with their nuclei centrally placed in each cell. A group of archegonial initials are recognizable near the pollen tube (pt). July 17, 1936. ×100.—Fig. 13. Transverse section of gametophyte in later stage, July 26. The body cell of pollen tubes have enlarged greatly, and the archegonia have cut off primary neck cells. ×100.—Fig. 14. Two parts of longitudinal section of gametophytes showing condition between that of fig. 12 and 13. Many potential archegonial initials are shown on the side next to the pollen tube (pt). July 26, 1936.  $\times 100$ .—Fig. 15. Section of pollen tube showing slightly enlarged body cell beside stalk and tube nuclei.

size of the mature seeds. The micropyles are now directed toward the cone axis. As figure 1 shows, the ovules are attached to the cone scale in two crescentic rows, and the resulting double row of ovules is still evident on the scale of a cone two-thirds grown (fig. 2). Figure 3 shows two fully enlarged ovules placed with their micropyles pointing upward and indicates that some ovules and

seeds are deformed or curved in several directions by local pressure during development. Figure 4 shows a section through an ovule and illustrates the lateral position of the archegonia and pollen tube, an unusual condition for conifers. The pollen tube enters the nucellus and grows into the position shown in the figures (fig. 4–6 and 11–13) long before the female gametophyte has become cellular.

The archegonia are produced on that side of the female gametophyte which is in intimate contact with the pollen tube. Figures 5 and 6 show the condition, as found in dissections of material shortly before fertilization, for an ovule with a pollen tube situated on its flat side similar in section to figure 11. More frequently the pollen tubes pass down close to the edges of the female gametophyte, as shown in

figures 12 and 13.

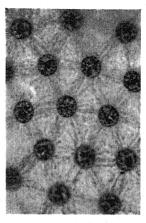

If the female gametophyte is removed from the ovule by dissection at a stage after fertilization, the pollen tubes will usually be found adhering to its surface and appear to be imbedded in a groove, as shown in figure 5. Of course the megaspore membrane separates the pollen tube from the surface of the female gametophyte. The pollen tube is firmly attached by the fertilization tube slightly above or near the mid-point of the female gametophyte so that the upper portion of the latter may be removed, as in figure 6, without disturbing the embryo. Both the megaspore membrane and pollen tube become very thin near the fertilization tube, and openings are formed through both at the time of the entrance of the male nuclei. The pollen tube is slightly enlarged at this place, and its end may extend downward for as much as 0.4 mm. below the fertilization tube, remaining somewhat smaller above and below this point of attachment. In some cases the fertilization tube is formed nearer the end of the pollen tube, giving a shorter "tail."

The earliest stages in the development of the pollen tube were not observed. Since the pollen grain is binucleate at shedding, there is only a single cell division which takes place before the stage shown in the transverse section of a tube, figure 15, where we have an enlarged body cell beside the stalk and tube nucleus. Both of the last named nuclei are without cell walls surrounding them. One of the pollen tubes in figure 11 is in very nearly the same stage, while figure 13 shows the body cell greatly enlarged about ten days prior to fertilization. Looby and Doyle report that they observed the division of the body cell and show that male gametes are formed as in Taxodiaceae and Cupressaceae. Evidently the gametes do not consist of

naked nuclei as found in pines.

As in other conifers, the early stages of the female gametophytes of Sequoia are free-nuclear. In early stages the nuclei are situated at the periphery very close to the megaspore membrane surrounding a very large central vacuole. In one of the ovules studied, the writer counted about 900 free nuclei. The oldest free-nuclear stage which could be found showed close to 4,000 free nuclei, while the stage in which walls have just begun to form (fig. 8, 9) had more than 6,000 nuclei, so that one may estimate 12 or 13 simultaneous divisions before walls begin to form in the female gametophyte. Mitotic stages were not observed during the free-nuclear stage, and there appeared to be occasional differences in the sizes of the nuclei of the last stages; therefore, there may be a ques-

tion as to whether or not all the divisions—that is, up to the last mitosis-occur simultaneously. Figure 16, a photomicrograph of the dissected surface of the megaspore membrane at the time of wall formation, indicates a very regular spacing between these nuclei and, with few exceptions (not shown), a great uniformity in their size.

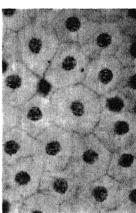

Fig. 16, A and B.-A (left). Surface view of megaspore membrane showing free nuclei spaced in pattern with phragmoplastic connections, before the appearance of cell walls.-B (right). Similar view after cell walls have begun to form.

Figure 7 shows a sectioned portion of the megaspore membrane with the adhering fringe of free nuclei in a late stage before walls are formed. At this stage the center of the gametophyte has a large clear vacuole (v). Wall formation begins at the periphery, as shown in figures 8 and 9. The former is a section through a place one-third of the distance from the tip of the nucellus and the latter about two-thirds this distance from it. Figure 16a is a photomicrograph of a dissected specimen just before walls appear. It shows a beautiful pattern of phragmoplastic connections developed between all neighboring nuclei. Figure 16b shows a subsequent stage after walls have become visible. This corresponds to the stage shown in figures 8 and 9. Figures 10 and 11, taken at different levels of the same gametophyte in slightly later stages (fig. 10 below the pollen tubes and fig. 11 through two pollen tubes), show that the nuclei, which are very close to the megaspore membranes, move inward as the walls are formed and tend to remain opposite the newest portions of the walls until the individual cells become closed; after this they become more centrally placed in each cell (fig. 12). It will be noted that many cells become crowded and are closed before the center is approached. Sometimes a central space remains for a time but becomes closed by elongation of the newly formed cells. Figure 14 shows a longitudinal section in which nearly all the cells touching a pollen tube (pt) have been delayed in their division in the region where archegonia appear.

Archegonial initials appear very early and are found in large numbers on the side of the megagametophytes adjacent to the pollen tubes. The initials are the first walled cells. Some of these may subdivide to form ordinary cells, others persist for a time, appearing as larger cells containing large nuclei in a dense cytoplasm. If they cut off smaller primary neck cells, as shown in figure 13, they have progressed another step in differentiation as archegonia, but some become partitioned into several or many smaller cells. The neck cell divides into two cells and finally forms a neck of four cells, as shown by Looby and Doyle (1937). Archegonia that become diverted to form ordinary gametophytic cells later may, in certain stages of becoming partitioned, give the appearance of enlarged jacket cells. The matured archegonia may appear in groups with only a cell wall dividing them, but there is no specially differentiated jacket that wholly surrounds such a group; therefore we do not find the type of archegonial complex observed in Cupressaceae.

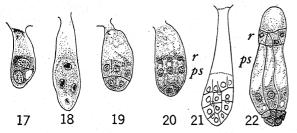

Fig. 17-22. Stages in the proembryo of Sequoia gigantea; r, rosette; ps, prosuspensor. After Looby and Doyle (1937). ×100.

Nearly all the irregularly scattered jacket cells derived from archegonial initials that have been recently partitioned disappear before fertilization. Very soon after fertilization, the unfertilized archegonia either collapse or become partitioned so that few traces of them may be found in gametophytes with embryos that are a week old. However, the pollen tube persists and may be found for many months afterward.

During the development of the female gametophyte, many nuclei may be observed in mitosis. The number of chromosomes counted during this haploid

stage is eleven.

The method of development shown by the female gametophyte (fig. 8–12) confirms Arnoldi's observations (1900) and adds other details. He described this method of "endosperm-formation" as alveolar and simultaneous throughout the female gametophyte in contrast to the method which he had previously observed in S. sempervirens (Arnoldi, 1899a) in which the two end regions of the gametophyte become differentiated from the central region. The free nuclei that are found in the end regions are spaced evenly throughout the gametophyte before walls are formed simultaneously between all nuclei, and only the central part forms the alveoli which develop centripitally around a

central vacuole. As shown in figures 7 to 14, the megaspore membrane is thick and very conspicuous. It is thickened at the basal end of the female gametophyte and becomes somewhat thinner as the micropyle is approached, is two-layered, and ranges in thickness from 2 to  $3\frac{1}{2}$  microns.

In S. sempervirens several investigators have reported the occurrence of numerous female gametophytes within the same ovule. It appears that these come from as many megaspores and compete with each other so that all but one or a few are eliminated. Naturally I sought for evidence of this type of development in S. gigantea, but no traces of a second female gametophyte were found even in the earlier free-nuclear stages. If this feature occurs at all, it takes place only in a very early stage of development.

Although by cutting more material I could add additional details concerning the earlier history of the development of the gametophytes and archegonia, my collections were not made frequently enough to close all the gaps in the series. Therefore, since Looby and Doyle have suggested that they still have some of these additional details under investigation, we may await with interest the

results of their researches.

THE EMBRYO.—For the stages which include fertilization and the proembryo the very full account of Looby and Doyle (1937) may be summarized. As mentioned previously, these investigators have demonstrated the important fact that in S. gigantea, there are several free-nuclear divisions in the early zygote as in Cunninghamia, Cryptomera, and other conifers. In respect to this feature, the Big Tree differs radically from its supposed close relative S. sempervirens, in which a cell wall is formed after the first division of the zygote. Figures 17 to 22 are successive stages taken from Looby and Doyle indicating that the first walls are formed after 8 free nuclei have been formed and that these nuclei and the cytoplasm of the egg at this stage occupy the lower half of the archegonium. The proembryo is organized into three or four tiers of cells. The lower tier at the stage of figure 20 is commonly 3-celled or 2-celled and the upper tier which divides again is 5-celled or 6-celled. Subsequent division may occur at both ends of a proembryo, forming an extra tier such as that shown in figure 21 and other exceptional cases, so that a group of rosette cells in one or two tiers is formed above the tier of 5 or 6 elongating cells; also the 2 or 3 embryonic cells situated below the elongating cells increase to form a group of at least 5 or 6 cells.

It appears that the cells of the rosette group may become enclosed by cell walls with an open space above, or they may proliferate to fill out more of the upper part of the archegonium. This may add irregular tiers of cells in the rosette. The central tier soon begins to elongate, thrusting the lower group of cells, as they increase in number, deeper into the tissue of the female gametophyte. Looby and Doyle did not follow the embryogeny beyond

the stage shown in figure 22, merely reporting that some type of polyembryony ensues.

Figure 23 shows an embryo of this early stage which is still associated with the pollen tube. Here all the cells of female gametophytes were omitted, but no rosette cells could be found. This embryo is smaller than most others of the same stage, and the terminal group of cells is still composed of only four cells. Any of the cells in these stages may collapse, which would account for some of the irregularities in cell number and arrangement.

As in my descriptions of certain other conifers, the elongating suspensor cells constitute a prosuspensor—a group of cells represented by a distinct tier of cells in the proembryo, elongating in unison and constituting a specially differentiated part of the entire suspensor system. Figure 24 shows two neighboring zygotes with their prosuspensors elongating. The one at the left has formed a large irregular group of rosette cells, crowded into the upper part of the archegonium; the one at the right, a smaller rosette with an open abortive space above. Four or five cells are found below in the terminal

embryonic group.

Figure 25 is a similar but larger and slightly older pair of embryo systems coming from larger archegonia. There are well developed rosette embryos and also some free nuclei above them in the remaining portion of one of the archegonia. The terminal group of cells has increased here to 8 or 9. A later stage is shown in figure 26. The prosuspensor has become long and twisted, and there are many more cells in the terminal group. This embryo system has only a few rosette cells, one of which has formed a rosette embryo. Thus we find considerable variation in the extent to which the rosette is developed. All the foregoing stages were found in collections of August 18, while the next stages were collected on September 8, an interval of more than two weeks. Figure 27 shows the smallest embryo complex which could be found in the collection of September 8. It shows traces of collapsed prosuspensors (ps) with more than a dozen individual embryos growing on their own primary suspensors (s), and some other peculiar embryos (probably developed from the rosette cells), pushed back against the crushed prosuspensor (ps). Evidently the individual cells visible at the tip of a prosuspensor such as that of figure 26 have each given rise to a terminal embryonic cell and a primary suspensor cell. The primary suspensor cells (s) have elongated greatly, while each of the embryonic cells has divided into two or three cells to form the complex mass of embryonic material of figure 27.

Figure 28 represents a stage collected nearly a month later. Only the lower portion (about half) of the greatly folded suspensor system is shown. The older parts have all collapsed, including the primary suspensors, portions of which are shown above at s in this figure. Embryonal tubes of the first, second, and third order  $(e_1, e_2, \text{ etc.})$  have ap-

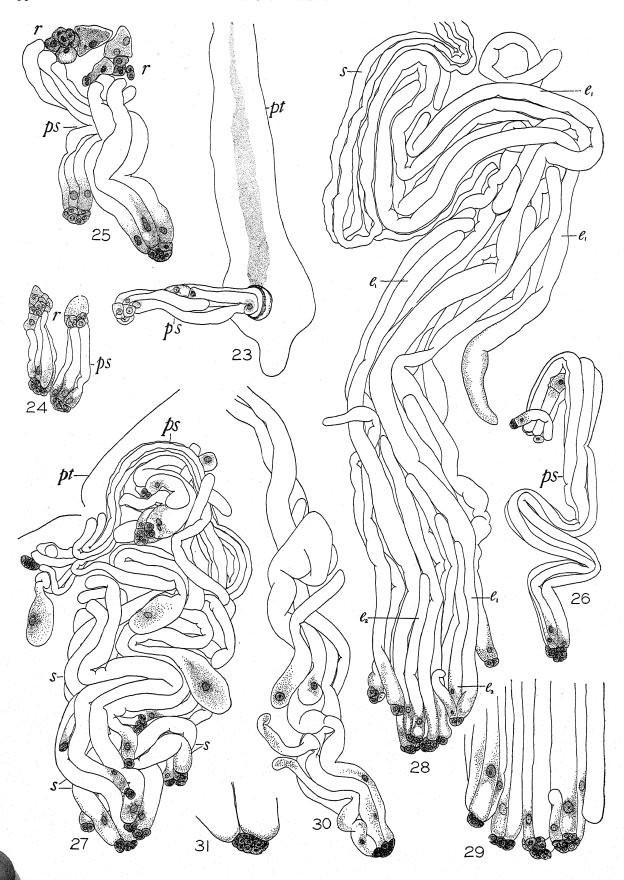

peared, so that now each embryonic group is borne on the end of a secondary suspensor composed of two or three embryonal tubes. The longest of the embryonal tubes are the oldest; the shorter ones may in many cases be traced throughout their length. Embryos may become aborted or dissociated at any stage.

Some of the smaller embryos shown here on a single suspensor segment probably originated from an unequal fractionation of larger embryos, a sort of secondary cleavage or "budding." For instance, the two embryos shown at the extreme left and right of the group in figure 28 are on suspensor segments which, as they are traced upward, do not reach all the way back to join even the primary suspensors (s), not to mention the prosuspensor, which would require more than twice this space for portrayal. These embryos were evidently derived from lateral lobes that were split away from the larger embryos and in breaking away included an elongating embryonal tube. The latter is now the single-celled suspensor segment to which they are attached. Then when the embryonic cells of these fractions abort, there may result a lone elongated cell.

Many embryonic cells were found isolated among the folds of collapsed primary suspensors, and there were some in the central and lower region of figure 28, which were not shown because they were covered by the mass of embryonal tubes,  $e_1$ ,  $e_2$ , etc. Furthermore, in these and later stages there were often many very small embryos which grew out of the gametophyte to become imbedded in the nucellus at the level of the fertilization tube. These were probably derived from rosette embryos. Small embryonic fractions, regardless of their origin, gradually become aborted, so that the number of sizable embryos remaining in the terminal group becomes smaller and smaller with time.

Figure 29 shows a stage similar to that of figure 28, with the terminal embryos somewhat older. Figure 30 is a single embryo and its secondary suspensor of the oldest stage collected October 15. Usually the embryos do not become much larger than this one, passing the winter in this or a similar stage. Figure 31 shows the tip of an embryo which was dissected from the softened ovule of a herbarium specimen collected by Mr. W. T. Frost on November 22, 1934 (University of California Herbarium).

The early embryo of S. gigantea appears to grow by means of an apical initial cell. The apical cell is not as conspicuous as in some other conifers and persists only long enough to form a half dozen segments or even fewer. The primary embryo divides into a primary suspensor cell and an embryonic cell; this embryonic cell may be considered as a hemispherical apical cell and the primary suspensor its first segment, which elongates and pushes the embryonic cell forward. Meanwhile the apical (embryonic) cell divides by a vertically placed wall; one of the daughter cells is the segment, the other is the apical cell. The segment soon elon-

gates, becoming an embryonal tube  $(e_1)$ , and the apical cell divides again and again cutting off segments on several sides. These segments may divide and elongate wholly or in part as embryonal tubes  $(e_2, e_3, \text{etc.})$ . The segments are not easily recognizable because some become elongated embryonal tubes. The apical initial usually persists at least to the end of the growing season when growth is checked by winter.

The next stages observed were before and at the time of formation of cotyledons. I am not including figures, since I observed only about a dozen healthy ovules in these stages. The cotyledons are formed late in July of the year following fertilization. A stem tip primordium is recognizable at the tip of a cylindrical embryo of several hundred cells; which is soon surrounded by a circle of about four cotyledon primordia. The embryo develops rapidly during August and September of the second year, so that the seeds are morphologically mature at the end of the second season following fertilization. In spite of the extensive cleavage polyembryony, nearly every seed has only one surviving embryo.

That the Big Tree is polycotyledonous may be observed in seedlings. The average cotyledon number in 73 seedlings was found to be 3.7. Five had 5 cotyledons, 40 had 4 cotyledons, 28 had 3 cotyledons. None of the 73 had fewer than 3 cotyledons.

The position of the archegonia is near the midpoint of the female gametophyte, but the latter continues to grow considerably throughout its lower half, thus crowding the upper portion. This belated growth includes an elongation of the nucellus and also an increase in its diameter. These structures are crowded upward into the space between the integuments. In the older stages collected in October, the upper part of the wall of the nucellus is usually so crowded that it has become folded transversely and wrinkled, and by the time the seed matures one would scarcely suppose from the position

of the embryo that fertilization took place so near the middle of the gametophyte.

From the drawings and magnifications given, it may be noted that the embryos of S. gigantea are very small. Whether we take one of the embryonic cells of figure 23 or one of those in figure 27, there is not a great variation in cell size. We may consider either of these embryos still essentially onecelled, since the cells in excess of one will all go to form suspensor-like embryonal tubes. If we consider the one-celled stage from figure 27, where it may be seen in the center of the lower group of primary suspensors (midway between the two lower S markers), and estimate its volume, we find this to be about 20,000 cubic microns. Thus in the Big Tree which may eventually reach a volume of 1,640 cubic meters (estimated for the General Grant Tree), the organism enlarges  $82 \times 10^{15}$ -fold.

It is difficult to comprehend the magnitude of this figure, so that it may be interesting to make a comparison with objects of appreciable size. I have made a computation using the size of the earth for comparison and found that the mature specimen of S. gigantea is as much larger than its embryo as the earth is larger than a building similar in size to the dome of the Adler Planetarium.

Discussion.—The development of the female gametophyte of the Big Tree follows the usual program found in other conifers. A long free-nuclear stage involving a succession of 12 or 13 divisions is found in its development, and the archegonia are laterally placed. These prothallia develop singly rather than in competition with other female gametophytes as in the redwood.

The megaspore membrane, which is two-layered and very distinct in *S. gigantea*, is not so thick and well developed as in Pinaceae, nor so thick as in certain other conifers such as some of the podocarps.

The writer has reported that the potential archegonial initials are very numerous, involving nearly all the cells in certain regions bordering on

Fig. 23-31.—Fig. 23. Early embryo system (dissected) still associated with pollen tube (pt); ps, prosuspensor. August 18, 1936. ×100.—Fig. 24. Two neighboring zygotes probably resulting from fertilization of neighboring archegonia by same pollen tube; r, rosette cells; ps, prosuspensors bearing a group of embryonic cells below. August 18, 1936. X100.—Fig. 25. Two similar zygotes in slightly later stage showing twisting prosuspensors (ps) bearing an increased number of cells in the embryonic group below. The rosette groups (r) above have divided with free nuclei still showing in upper portions of archegonia. August 18, 1936. ×100.-Fig. 26. Older stage with prosuspensor (ps) considerably elongated, about 10-12 embryonic cells below and only a few rosette cells or embryos above. August 18, 1936. ×100.-Fig. 27. Much older stage of development than fig. 26 after cleavage of the group of embryonic cells shown in fig. 26. Each embryo is found borne on its own greatly elongated primary suspensor (s) which has pushed back the collapsed prosuspensor (ps) shown above. Rosette embryos may be seen scattered about in the upper portion of this figure (pt, edge of a pollen tube). September 8, 1936. ×100.—Fig. 28. Lower portion of an embryo complex after the primary suspensors (s) have begun to collapse. Each embryo unit is now borne on one or more embryonal tubes, whose order of origin and elongation  $(e_1, e_2, \text{ etc.})$ are indicated by their lengths. At this stage it is very difficult to identify the completely collapsed prosuspensors, and only some of the primary suspensors could be traced. Many small embryos, probably rosette embryos, are scattered about in the collapsed upper portion, omitted from the drawing. October 5. ×100.-Fig. 29. Tip of an embryo complex similar to fig. 28. October 11.-Fig. 30. One of the oldest embryos obtained on October 15 singled out to show the succession of embryonal tubes from the secondary suspensor. The upper portion of the suspensor probably represents  $e_1$  and  $e_2$ . There are approximately 12-15 cells in the embryo below. This is approximately the condition found at the approach of winter. October 15. ×100.-Fig. 31. Tip of an embryo slightly older than fig. 30, taken (with permission of curator) from a dried specimen found in the University of California Herbarium collected in Sequoia Park by W. J. Frost on November 22, 1934. X100.

the pollen tubes. Of course it is possible that they are actually not so numerous and that I have been unable to distinguish such initials morphologically from other large cells in that position. However, it must be remembered that very many of these divide unequally to cut off primary neck cells and larger central cells, thus closely resembling the archegonia of other conifers at this stage. Many of these develop no farther and finally subdivide into ordinary gametophytic cells; in a smaller number the primary neck cell divides into two neck cells; a few into four neck cells, as Looby and Doyle (1937) have shown. The work of these authors does not show that a ventral canal cell or nucleus is formed. I have found none, but the archegonia in my own material may have been too immature to include this stage if it is present. Ventral canal nuclei have been reported in related genera so that one would expect to find them in Sequoia, but thus far their occurrence has not been demonstrated.

The embryogeny of S. gigantea resembles, in general, that of Sciadopitys (Buchholz, 1931) more nearly than that of any other conifer. In Sciadopitys there is at least one more free nuclear division; Lawson (1910) shows a section through a proembryo with six of the eight free nuclei, so that one may judge that walls may form after the 8 free nuclei have divided to give rise to 16. The archegonia are very much larger in Sciadopitys, terminal in position, and not grouped into an archegonial complex. Another difference is that the embryo of Sciadopitys is usually dicotyledonous, but has three cotyledons occasionally, while that of S. gigantea is tetracotyledonous.

Aside from these important differences, the similarities in embryogeny between the Big Tree and Sciadopitys are very striking. Both form a prosuspensor, which is somewhat ephemeral in the Big Tree; both have rosette embryos, not constantly present in Sciadopitys and relatively better developed in S. gigantea; both have a similarity in the formation of the primary embryos from the initials borne on the end of the prosuspensors. The details involving the formation of primary suspensors, and the apical cell growth in each embryonic unit are similar.

The embryos, borne on primary suspensors, appear different only as to relative proportions. The primary suspensors and embryonal tubes in Sequoia are more slender than in Sciadopitys, and there appear to be a larger number of successive additions of embryonal tubes.

When the embryogeny as given here is compared to that of the redwood, S. sempervirens, as pieced together from the accounts of Shaw (1896), Arnoldi (1900), Lawson (1904), and others, many important differences are discovered. These differences will be discussed more fully in a subsequent paper in which the writer has included his own investigations on the redwood. It will be shown that the embryo of S. sempervirens, aside from having no free nuclear stage in the proembryo, omits the

prosuspensor entirely. There are also many other features in which the two species of *Sequoia* differ; in fact, it may be shown that the two species are so far apart in respect to these morphological criteria that they should be regarded as belonging to separate genera.

### SUMMARY

The general morphology of the ovule of S. gigantea, its relation to the cone scale, and the position of the gametophytes in the ovules of a cone which is nearly full grown are briefly described.

The development of the female gametophyte is described with reference to the extent of the free nuclear stage, followed by an alveolar type of centripetal development, the origin of archegonial initials, and their relation to the position of the male gametophyte. Archegonia have their origin in the first walled cells that are formed in a position adjacent to the pollen tubes; very many potential initials are found developing only to the two-celled stage, though relatively few develop fully into matured archegonia.

Archegonia are usually grouped into an archegonial complex or into several such groups, which differ from those of the Cupressaceae in the absence of jackets.

The mitotic figures observed in the female gametophyte permitted the counting of 11 chromosomes as the haploid number in S. gigantea.

The male gametophytes were observed with the usual large body cell, a stalk, and a tube nucleus. They form a fertilization tube which connects with the pair of archegonia that are fertilized.

The megaspore membrane is composed of two layers and is of considerable thickness—between 2 and  $3\frac{1}{2}$  microns.

As Looby and Doyle have shown, the embryo begins its development with free nuclear divisions; 8 nuclei are present when walls are formed. The proembryo fills the lower half of the egg and may eventually fill the entire archegonium. It is organized into tiers, a rosette tier or region which may include several tiers, a tier forming a prosuspensor, and a group of two or three cells below the prosuspensor which, by their further division, give rise to embryo initials.

As it elongates, the prosuspensor pushes the terminal group of embryonic cells forward, while the latter multiply to become a group of 8 or more embryo initials. The embryo initials cut off primary suspensor cells which elongate rapidly, soon pushing back and crushing the prosuspensor. The terminal embryo units divide by apical cell growth to form successive segments, the oldest of which forms the primary suspensor, followed by a succession of later-elongating embryonal tubes. Some segments borne on embryonal tubes may become dissociated and develop independently. Cleavage polyembryony is therefore very extensive, resulting in a large number of embryos per zygote.

As the end of the first growing season is reached, the embryos are still composed of only a dozen or more cells, entirely undifferentiated except for the polarity shown in the embryo-suspensor axis.

The number of surviving embryos decreases; finally during the following spring the successful embryo becomes larger, develops into a cylindrical mass, and forms about four cotyledons in July-August of the second year, thus reaching maturity only by the end of the second season of its development.

In general, the embryogeny resembles that of Sciadopitys more nearly than that of any other conifer thus far investigated and appears to differ in many important features from the embryogeny of S. sempervirens.

# A NEW METHOD FOR THE CONSTRUCTION OF THREE-DIMENSIONAL CELL MODELS

#### James W. Marvin and Edwin B. Matzke

In a study of the shape of pith cells, a new method has been developed by which accurate three-dimensional models of individual cells may be constructed. The procedure consists essentially of making casts of hard wax of the cells, separating these casts, drawing each face of a cast by means of a camera lucida on bristol board, and then reconstructing the cell on a large scale by fitting the pieces of bristol board together.

Apparently the only technique thus far used in the careful study of the shapes of cells in tissues is Born's wax-plate method, utilized with marked success by Lewis (1923). This involves cutting the cells into serial sections, modeling each section in wax, and then rebuilding the cells in three dimensions by stacking the wax plates in sequence. The method to be described deals with the cast of the entire cell, rather than with numerous serial sections of a single cell.

The pith is first removed from a portion of an internode of a stem by carefully cutting away most of the external tissues. A strip of these tougher outer cells is left to afford rigidity. The section of pith is then immersed in absolute ethyl alcohol and placed in a partial vacuum chamber to aid in the removal of air. After the tissue is completely

<sup>1</sup> Received for publication January 11, 1939.

saturated with alcohol, it is transferred through three alcohol-xylol mixtures to xylol. The first mixture contains two parts of alcohol to one part xylol; the second contains equal parts of alcohol and xylol; the third consists of one part alcohol to two parts xylol. After one to two hours in each mixture, the material is transferred to pure xylol, in which it remains for twenty-four hours, with several changes.

The next step is impregnation with purified Montan wax, which is a lignite derivative with a melting point of about 85°C.<sup>2</sup> It is hard but not brittle at room temperature. This wax is soluble in warm xylol, and impregnation is accomplished by pouring a small amount of the melted wax into a vial of xylol containing a section of the tissue and placing the vial in an oven. After a few hours, more wax is added. Later, the xylol and wax mixture is poured off, and pure wax is substituted. This is changed once a day for three days, after which the material is removed from the vial of melted wax and placed in ice water.

The wax on the surface of the mass of cells is then removed with a razor, and the material is im-<sup>2</sup> This is one of a number of possible waxes kindly

suggested by Mr. John Leutritz, Jr., to whom grateful acknowledgment is here made.

mersed in cuprammonia. This is made by covering copper filings with ammonium hydroxide (Stevens, 1924). The material remains in this solution for a time sufficient to allow the cell walls to become mucilaginous. It is then thoroughly washed in water and is ready for examination. According to Farr (1938), the cotton fiber is transformed by cuprammonium hydroxide solution into a swollen viscous mass of cementing material containing the cellulose particles.

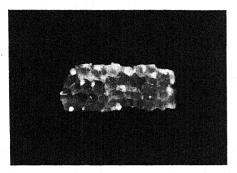

Fig. 1. Wax casts of a group of cells from the pith of Eupatorium purpureum L.  $\times 30$ .

Under a high power binocular dissecting microscope the individual cells are easily distinguished. They appear as shown in figure 1. The lumen of each cell is filled with wax which is stained a pale blue by the cuprammonia. With a pair of fine needles the wax casts of the cells can be separated from each other, each wax cast still surrounded by its cell wall. When dry, the cell wall is easily seen. The mucilaginous character of the cell wall when wet makes it possible to attach the cast of the cell to the tip of a fine glass bristle or thread.

The glass bristle, which is "L" shaped, is attached to the manipulator shown in figure 2. It appears as a thin black thread-like line in the illus-

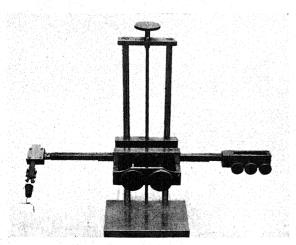

Fig. 2. Manipulator used in orienting individual cells under binocular dissecting microscope. Description in the text.  $\times \frac{1}{16}$ .

tration and is mounted so that turning the short arm of the "L" revolves the bristle on its long axis, to the tip of which the cell adheres. The long arm of the glass thread is oriented perpendicularly to the rod to which it is fastened. The rod is thrust into a cork which is held by wire forceps. The cork and rod can be rotated on their long axes by a geared adjustment. With these two movements the cell can be moved in two planes. In addition, the entire arm on the left, including the bristle, cork, and forceps, is in turn attached at right angles to a second heavier horizontal rod which can be turned by gears, moving the bristle up and down in an arc. The heavy horizontal rod and consequently the glass thread can also be moved from right to left by a rack and pinion, as well as forward and backward and up and down by two other adjustments.

With this device it is possible to orient each face of the cell in sequence in the horizontal field of a high power binocular dissecting microscope. The outline of each face, thus oriented, is drawn with a camera lucida on bristol board. Then the faces are cut out and glued together in proper order to make a three-dimensional model of the cell, in a fashion similar to that used in modeling the orthic tetrakaidecahedron (Matzke, 1931).

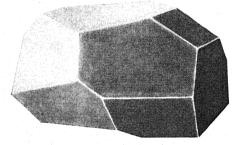

Fig. 3. Natural size drawing of a model of an unusually large pith cell of *Eupatorium purpureum* L. The original pith cell is magnified 170 diameters in the model.

From such a model the number of faces may be determined and also the number of edges per face and the number of dihedral, trihedral, and tetrahedal angles. In addition, it is possible to compute the surface area of the faces as well as the volume of the cells. A comparison of the cells of the original pith tissue with the wax casts indicates that the technique used causes no appreciable distortions and no changes of major significance in shape.

A drawing of a model of a pith cell of Eupatorium purpureum L. is shown in figure 3. The pith cell is magnified 170 diameters in the model, and the latter is drawn natural size. This matches the original cell, face for face. The number of contacts, fifteen, of which seven appear in the drawing, as well as the kind of contact—whether triangular, quadrilateral, pentagonal, etc.—can readily be determined, and also the number of dihedral and trihedral

angles. The curvatures of some of the faces and edges are not reproduced in the model and are not shown in the drawing. This particular cell is an unusually large one, approximately twice the average length of the cells shown in figure 1.

Using the technique described above, studies of the pith of *Eupatorium purpureum* L. have been made, and similar work on other genera is in prog-

ress.

#### SUMMARY

A new technique is described for modeling cells in three dimensions, to be used in studying their shapes. The cells are impregnated with hard wax, the casts are separated, each face is drawn with a camera lucida on bristol board, and the pieces of bristol board are then fitted together in proper

order to build a scale model of the cell, much enlarged.

### THE CONCEPT OF SPECIES BASED ON EXPERIMENT 1

Jens Clausen, David D. Keck, and William M. Hiesey

The Linnean species concept was based upon the supposition that species are separate entities unable to cross or at least unable to produce very fertile hybrids. In his mature years, Linnaeus found by experiment that some species could produce partially fertile hybrids (1790), and he arrived at a concept of evolution of species by hybridization (Systema Vegetabilium, 1774). Unfortunately, Linnaeus' taxonomic followers did not heed his advice on experimental work, nor were they very much influenced by Koelreuter's (1761–1766) work on interspecific hybrids. Consequently, the early taxonomists emphasized the concept of the rigidity of species.

Jordan (1846) proved by experiment that races of one Linnean species from different environments remained distinct when grown in a standard garden. This discovery also left very little influence, because, in accordance with the prevailing beliefs, Jordan interpreted this to mean that each race was a distinct species. To taxonomists this appeared absurd, and they discredited the new experimental trend. Furthermore, Darwin's books diverted the energies of taxonomists from the experimental to a more philosophical approach, which culminated in the development of a "phylogenetic" system based on comparative observation alone.

As modern genetics developed in this century, it was rediscovered that hybridity is not a rare phenomenon and that many hybrids between species are partially fertile. This, together with the evolutionary philosophy, led to the extreme viewpoint that species after all are but abstractions of the human mind. This trend of thought, widespread among geneticists and physiologists, was nourished by the activities of a contemporary, non-experimental school of splitters among taxonomists.

<sup>1</sup> Received for publication December 16, 1938.

It is evident that the species problem is too complex to be solved by herbarium work alone and that the geographical and ecological methods, indispensable in all good descriptive taxonomy, are also insufficient. Cytological and genetical methods of themselves are just as limited, for species and other evolutionary units are closely connected with a natural environment. Very few cytologists or geneticists study their plants or animals except in the laboratory, and the forms studied are seldom representative of those found in any natural environment.

Moreover, in most genetic experiments performed with plants from natural environments, there are two facts concerning truly interspecific hybrids which have not been duly emphasized. One is that only a small percentage of the genic recombinations survive, the other that vigor of the survivors is reduced, so that only few members of the second generation are fit for the severe competition in nature. There actually is a natural reason for the fact that although crossings constantly take place, the species have remained remarkably the same for centuries, as evidenced by herbarium specimens, and even for ages, as shown by geological records.

The writers have performed extensive experiments on several plant groups during a series of years, viewing the problems from morphologic, geographic, ecologic, cytologic, genetic and to some extent also physiologic angles. The largest body of evidence has been obtained from the Madiinae, a West American subtribe of Compositae. Out of some 400 hybrid combinations attempted, involving seventy species of six genera, about 200 succeeded, and the others were non-viable or complete failures. Similar experiments were done in a group of three species of Zauschneria (Onagraceae), in Potentilla

(Rosaceae), Viola, and various other genera. Many illuminating data have been obtained from a study of the reactions of many plant species transplanted to different climates. Also, the literature on interspecific hybridizations from the last two decades abounds with evidence on the nature of species, although the taxonomically important information has not always been emphasized.

Here is not the place to enter into a detailed discussion on the nature, composition and evolution of natural species. This is the subject of volumes in preparation based on our detailed experiments. It is sufficient here to state that plants are organized into groups, the members of each of which are able to interchange their genes freely in all proportions without detriment to the offspring. Such groups are separated from one another by internal barriers that are of a genetic-physiologic nature (including chromosomal barriers) that prevent such free interchange. These natural groups correspond fairly closely to the species of the moderately conservative taxonomists working with plants that reproduce sexually.

This criterion for species, now substantiated by experiment, is the same that Turesson (1922) previously applied to the ecospecies. Consequently, we use his terminology to distinguish species whose status has been determined by experiment. The ecospecies becomes the experimental homologue of the taxonomic species. Also Dobzhansky (1937) has recently called attention to the importance of the internal ("physiologic") barriers separating species, noting that commonly they coincide with the delimitations of the species as accepted by systematists.

For simplicity, the experimental concept of species has been put in tabular form.<sup>2</sup>

Admittedly it is impossible to produce definitions that will cover all differences between systematic units, because species are in all stages of evolution. Nevertheless, this classification is based upon criteria of superior importance for the continuation of

<sup>2</sup> The principles for this classification were presented in a symposium before the American Association for the Advancement of Science in St. Louis, January, 1936, and also elsewhere (see literature references).

the species in nature. Also, it provides a scale permitting us to evaluate natural units in transition between ecotype, ecospecies, and cenospecies. It limits subjective judgment to a fair minimum, making possible a comparison of various types of species characteristic for different parts of the world.

The degree of separation used in this system of classification is based upon two kinds of barriers internal (hereditary) and external (environmental). The internal barriers are possibly all geneticphysiologic, expressed through incompatibility and intersterility or through weakness of the hybrid offspring. Ultimately, it is probably the genes that govern the rates and inception of the metabolic processes that are so evidently off-balance in offspring of interspecific hybrids. The external barriers are either ecologic or geographic. A distinct geographic barrier is likely also to be ecologic. The most permanent barriers are the internal, because they persist even though the environment changes in a changing world. They are therefore used in distinguishing species. A qualifying statement as to the internal barrier is necessary. Two forms may prove intersterile by direct test, although they interlink through one or several intermediaries that are interfertile with both. The barrier separating such forms is not considered specific, because genes may be exchanged through the intermediary.

Cenospecies.—If the genetic barrier is absolute, it separates groups so perfectly that they are able to exist together in one environment without intermixing. This kind of barrier is characteristic for individuals belonging to different cenospecies or species complexes. The cenospecies are groups of major evolutionary importance, comparable to but not at all identical with the taxonomic section, and may contain from one to many ecospecies. Members of different cenospecies may cross, but the hybrids are sterile unless doubling of chromosomes (amphidiploidy) takes place, in which circumstance a new species has evolved—a new step in the evolutionary process.

Ecospecies.—If the genetic isolation is only partial, we usually find that there is an additional geographic or ecologic isolation. This kind of separa-

TABLE 1. The concept of species.a

Degree of separation  Internal  External	Hybrids fertile, second generation vigorous	Hybrids partially sterile, second generation weak	Hybrids sterile or none
In different environments	Distinct subspecies ECOTYPES	Distinct species ECOSPECIES	Distinct
In the same environment	Local variations of one species BIOTYPES	Species overlapping in common territory (with hybrid swarms)	species complexes,  CENOSPECIES

<sup>&</sup>lt;sup>a</sup> The systematic units based on experimental evidence are in capitals, their homologues based on external characteristics are in italics.

tion, partly genetic and partly ecologic, is characteristic of ecospecies of one cenospecies. The ecospecies correspond to but are not always identical with the taxonomic species. To a limited extent, ecospecies of one cenospecies can exchange genes across the barriers, and they may show parallel variation on account of this exchange through the ages. If crossed, their hybrids are partially sterile, whereby non-viable sex cells are eliminated, or the second generation offspring is weak; most often both these conditions obtain. Weakness of the second generation may manifest itself in various ways: many individuals are slow-growing dwarfs, or subnormals; others are very susceptible to diseases to which the grandparents and even F<sub>1</sub> are immune; others again may be structural or anatomical misfits, to mention some examples. Any one or all of these weaknesses may characterize a hybrid population. In a world with strong competition such misfits have few chances of survival. A small percentage of the total offspring may be vigorous and fertile but tends to be eventually absorbed into one or the other of the parental species.

A group of ecospecies belonging to one cenospecies is found to inhabit a series of geographically or ecologically separated areas: one may inhabit a coastal region, another an inland region; one forested, the other open areas; one basic or alkaline, the other acid soils; one low, the other high altitudes; one a southern, the other a northern territory, and so on. In extreme cases, as in Salix or Viola, there may be as many as twenty or thirty ecospecies in one cenospecies. The genetic barriers between ecospecies are often produced by differences in number of chromosomes. Hybrid swarms may be found in nature where two ecospecies of one cenospecies meet or overlap.

ECOTYPE.—If there is no genetic but only geographic or ecologic isolation, the units are considered ecotypes of one ecospecies. They parallel, but are not nearly always identical with, the geographic subspecies. Ecotypes of one ecospecies may occupy a series of different habitats similar to that mentioned under ecospecies. The only difference between the two units is the lack of a genetic barrier between ecotypes. Like ecospecies, they differ by many genes. They hybridize freely where they meet, but at a distance from the point of contact they are quite pure. Ecotypes are evidently the forerunners of ecospecies, and there is no absolute gap between the two. Only a few cases, however, are truly intermediate and difficult to classify, and they are but a small fraction of the doubtful cases that arise in classification based exclusively on external appearance. They are inevitable in a dynamic, changing world.

LOCAL VARIATIONS. — Taxonomic classification stops with ecotypes. Within an ecotype or a subspecies, variation may be found of the kind that characterize different individuals of one population, or of a series of populations, in one kind of an environment. Neither external nor internal bar-

riers separate them. They hybridize and recombine thoroughly; millions of different combinations of these variations are possible in almost any species. They are the biotypes of genetic terminology, and it is obviously impossible to give taxonomic recognition to all these variants. Evidently they have very little selective value, otherwise they would not appear at random. In morphologic appearance some of these variations are very spectacular and have previously received wide taxonomic recognition, but we consider them only local variations not intended for inclusion in any taxonomic system.

Principles and application.—Two factors that are of great importance for living things are taken into consideration in this classification: the environment in which the organism lives, and the heredity, which must fit in the environment. Differences in form, long taken as the sole basis in classification, are now understood as important only as they mark genetic differences of various sorts, including those which have proved of selective value when subjected to the environment.

Ecospecies, ecotypes, and local variations are all based upon hereditary differences, but only the former two show any correlation to the environment. Differences in heredity cannot be seen directly but must be established by experiment. The simplest experiment of this kind is to grow samples of natural populations in a uniform garden. This eliminates the gross environmental differences and makes it possible to compare the heredity. The analysis of the heredity, however, can be undertaken only by hybridization experiments.

The morphological characters which taxonomists use in their classification have often been discredited as being of no importance in the life of the plant. This may be correct if we consider the characters by themselves, but our experiments show that they may be closely correlated to the physiologichereditary complexes on which ecotypes are based, such as earliness and capacity for survival in certain environments. Also, there is often an absolute correlation between morphological characteristics and the chromosome number or other internal barriers that separate species. When experiments have established the correlations, such character complexes become important indicators or key characters that can be used in tracing the distribution of ecotypes and ecospecies in the field and in mapping them with the aid of herbaria.

In asexually reproducing organisms, the present species criterion cannot be directly applied, although even among facultatively apomictic plants the number of successful hybrid combinations is very limited as found from experiments performed where crossings are possible. In other words, favorable combinations are selected for survival in these plants as well as in purely sexual species. A greater number of successful combinations are possible among apomicts than among sexuals because their F<sub>1</sub> hybrids are multiplied asexually and circumvent the exacting test of sexual reproduction

with its recombination of the parental genes in all proportions. Information on chromosome numbers and distribution of sexual progenitors and apomicts will often aid in understanding the evolution of and

the species problem in these plants.

TERMINOLOGY.—Botanists have agreed upon an international terminology in nomenclature, to which all should adhere. Nomenclatorially, each ecospecies of a cenospecies and also the monotypic cenospecies that contain only one ecospecies become taxonomic species. The ecospecies is therefore the basic taxonomic unit in experimental work. This will not greatly change the historic species concept, as mentioned, except in territories where the flora is insufficiently known. For practical reasons, two or more ecospecies that have no morphologic characters to distinguish them may be treated as one taxonomic species. The statement should be made, however, that biologically this complex contains more than one ecospecies, because genetic differentiation has preceded the morphologic.

The next unit permitted in nomenclature under the species is the subspecies. It is therefore natural to use this unit as the taxonomic homologue of the ecotype. Moreover, the term subspecies is commonly used for units of geographic or ecologic importance. It is less committed than the term variety, which was originally employed by Linnaeus to cover what we now would call environmental modifications and is commonly used also for garden forms. As in ecospecies, it is sometimes necessary to include more than one ecotype in a subspecies, stating that it consists of certain ecotypes that appear ecologically important but are morphologically indistinguishable. The objective is to have limits of subspecies (a morphologic term) correspond to the limits of one or a group of several ecotypes (an experimental term).

Whenever experimental evidence is lacking, the terms ecotype, ecospecies and cenospecies should never be used but only their homologues: subspecies, species, and species complex. If taxonomists are unable to use the experimental approach, they may nevertheless follow the geographic and ecologic principle in their work. In so doing, they will lay a solid groundwork for coming experimental investigations. They will make additional progress if they are able to determine chromosome numbers of several populations of their systematic units. If these differ, an internal barrier has almost invariably been set up, which would justify treating the units as distinct species, provided the morphologic and geographic evidence warrants it. first and simplest step in an experimental investigation is the cultivation of races from different environments in a standard garden, as Jordan (1846) did more than ninety years ago. This, however, can never replace the powerful analytical tool, systematic hybridization.

## AUTONOMIC CYCLE OF RATE OF EXUDATION OF PLANTS 1

## Karl A. Grossenbacher

SINCE HOFMEISTER reported diurnal fluctuation in root activity in 1862, several investigators have substantiated his findings and attempted to obtain conclusive evidence as to whether or not such fluctuation represented a truly autonomic cycle. Studies in this laboratory have confirmed earlier work and, it is believed, have proved beyond doubt the autonomic nature of cycles in exudation.

White (1938) has recently reported that root pressure may reach very high values (greater than 6 atmospheres) and that there was a marked diurnal cycle in exudation of excised tomato roots. Unfortunately, he did not control light or temperature, so that it is not clearly demonstrated what the cycle he observed is related to.

In work reported elsewhere (Grossenbacher, 1938; Skoog, Broyer and Grossenbacher, 1938) in which considerable care was taken to control conditions during various tests of exudation and root pressure, results were obtained which indicated the existence of autonomic cycles. Complete proof of the autonomic nature of such cycles, however, must be dependent on obtaining control of the cycles. Otherwise, it is always possible to argue that changes in external conditions or some uncontrolled factor may be responsible for periodicity.

In order to study the nature of such cycles, plants were grown in the greenhouse and in cabinets (similar to those described by Davis and Hoagland, 1928) in which temperature, air flow, humidity, and light were under control.

Environments used.—(1) Greenhouse, "normal day"—without control; (2) cabinet A, "continuous day"—temperature 20°C.; relative humidity 70 per cent; constant air flow which, however, ranged from 0 to 100 feet/m. within various portions of the cabinet; light 100 to 300 ft. candles (12–300 watt lamps); (3) cabinet B, "inverted day"—identical with A, except that lights were off from 6 a.m. to 6 p.m.; (4) room C, "continuous night"—temperature 25°C.; relative humidity 90 per cent, gentle air circulation; and constant ruby light of low intensity; (5) temperature baths—continuous light (10 ft. candles) and temperature of 15° and 30°C.

Plants were grown in the greenhouse and in each of the two cabinets according to the usual solution culture technique. Each set represented 120 plants in 4 liters of half-strength Hoagland's solution (KH<sub>2</sub>PO<sub>4</sub>, 0.001 M; MgSO<sub>4</sub>, 0.002 M; KNO<sub>3</sub>, 0.005 M; Ca(NO<sub>3</sub>)<sub>2</sub>, 0.005 M). Iron and minor elements were added as needed. Seeds of Helianthus annuus (Russian Mammoth Sunflower) were planted in dry sand, watered, and placed in the cabinets or greenhouse. Seedlings were transplanted into solution after one week. Exudation

<sup>1</sup> Received for publication July 27, 1938. I wish to thank Prof. D. R. Hoagland and others in the Division of Plant Nutrition for their help and friendly criticism. tests were made with plants one to four weeks old in one or the other constant environments. (Cultures were continuously aerated during the test period.) The plants were cut off below the cotyledons, and short lengths of glass or rubber tubes were snugly fitted to the stumps (fig. 1). Exudates were

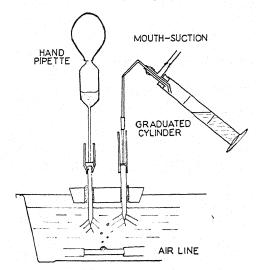

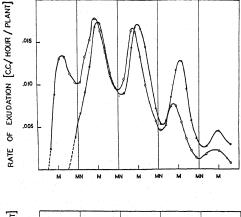

Fig. 1. Diagram illustrating methods of collecting exudates.

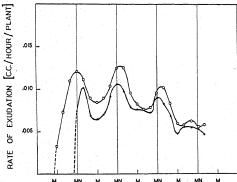

collected from these cups at three or four hour intervals for several days. Results are presented graphically in terms of rate of exudation (cc./hr./plant).

EFFECT OF LIGHT.—Results for the "normal day" plants are illustrated in figure 2. There was a pronounced cycle with maxima occurring during the day and minima during the night. Further, starting the tests one-half cycle apart caused no pronounced change in the time of their appearance or in rates of exudation. Similar results have been obtained in numerous experiments with normal greenhouse plants.

Plants raised under artificial conditions, with light during the night only, also showed twenty-four hour cycles (fig. 3). In this case, however, the maxima occurred during the artificial day and the minima during the artificial night (i.e., inverted day caused the cycle to be inverted).

It might be anticipated that there would be no cycle for plants raised under constant light conditions. Romell (1918), however, demonstrated that plants raised under continuous light did show a cycle. In his work this cycle coincided with that of plants grown under normal conditions. Here, however, five separate tests gave cycles which corresponded to those of inverted day plants. It was not until tests were started at different times of day that a possible explanation appeared. In figure 4

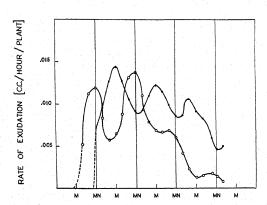

Fig. 2-4. Rates of exudation of plants decapitated at different times as indicated by dotted lines.—Fig. 2 (above). Plants grown in the green house.—Fig. 3 (center). Plants grown under condition of "inverted day."—Fig. 4 (below). Plants grown under condition of "continuous day."

it will be seen that the cycle may be as pronounced as in the previous cases, but that here, starting the test one-half cycle late shifts the time of maxima and minima by one-half of a cycle—i.e., it appears that when plants are grown under conditions of constant light, a twenty-four hour cycle is initiated by the process of decapitation.

The above curves represent data obtained in exudation tests made under constant high intensity light (cabinet A), but similar results were obtained

in constant low intensity white light (temp. baths) and ruby light (room C).

EFFECT OF TEMPERATURE.—Preliminary tests showed that exudation at 10°C. was so low that accurate measurements of rate were impractical. In an experiment presented as figure 5, "inverted day"

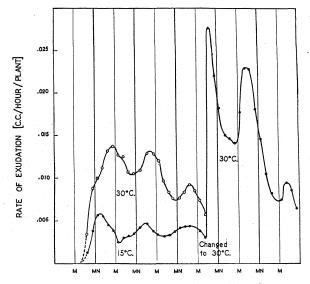

Fig. 5. Effects of temperature on rates of exudation.

plants were studied at 15° and 30°C. It is evident that temperature has a marked effect on the rate of exudation. At 30°C., exudation rate climbed to a high level and then fell rapidly, while at 15°C. the rate maintained a low value for some time. There are minor differences in the time of maxima and minima, but it seems possible that these may be due to secondary effects resulting from the difference in magnitude of the rate of exudation. The length of the cycle is only slightly, if at all, influenced by the temperatures at which the plants were tested. After three distinct maxima had been observed, the plants were transferred from 15° to 30°C. (the temperature of the solution culture being raised 15°C. in thirty minutes). This treatment resulted in an immediate maximum exudation, and subsequent maxima occurred at twenty-four hour inter-The general level of exudation was higher under these conditions than when the plants were placed directly into the 30°C. bath. The transition from 20° to 30° did not cause as large a stimulus as the sudden transition from 15° to 30°C. did. Plants grown in the greenhouse gave essentially similar results.

#### SUMMARY

Decapitated *Helianthus* plants show a definite autonomic cycle of exudation.

During the growth of these plants the twentyfour hour environmental cycle of a normal day or a twenty-four hour cycle consisting of successive twelve hour artificial light and dark periods can fix the time of day when the maxima and minima of the twenty-four hour exudation cycle occur. Under these conditions the exudation cycle is not materially affected by decapitation or slight temperature changes.

Plants grown under constant conditions show twenty-four hour autonomic cycles of exudation, but in this case the time of decapitation determines the time of occurrence of maxima and minima. A drastic rise in temperature during the exudation period will also determine the time of occurrence of maxima and minima.

The twenty-four hour periodicity of the exudation cycle is not materially affected by temperature and other treatments described.

## SOME EXPERIMENTS ON BUD GROWTH 1

#### F. W. Went

The literature on bud inhibition has recently been summarized in an excellent review by Thimann (1939); so a discussion of the different viewpoints on lateral bud growth can be omitted. The following experiments all bear on this problem and allow a further critical consideration of some theories.

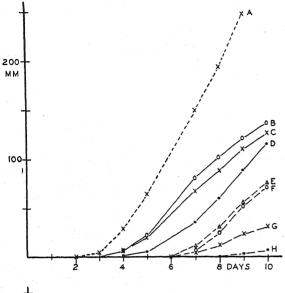

All experiments were carried out with etiolated stems of peas, *Pisum sativum* var. Alaska. They were grown in washed sand in a dark room at 24°C. and 85 per cent humidity and were used approximately seven days after planting, when the third internode was almost full grown. For the experiments the growth of the bud in the axil of the first or second bract was used. Care was taken to select only plants which were of the same length and development.

INCREASE OF INHIBITION WITH DISTANCE.—The results of the first experiments confirmed Snow's experiments on the increase of inhibition with increasing distance from the source of inhibition. Snow (1931a) in his experiments used the effect of the apical bud or leaves. But here this effect was replaced by auxin paste. Figure 2 clearly demonstrates that simple decapitation at various distances from the bud did not appreciably influence the outgrowth of the lateral buds. Neither did the distance have much effect when very low auxin concentrations were applied, which increase lateral growth compared with pure lanoline. This proves that the wound as such has little to do with it. But the higher auxin concentrations (0.2 and 1 mg. indole acetic acid per gram lanoline) were much more effective when the paste was applied 50 mm. instead of 5 mm. above the lateral bud (fig. 1, 2).

<sup>1</sup> Received for publication October 1, 1938.

A significant observation can be made by calculating the growth of the inhibited plants of figure 1 in a different way. If the growth curves of the individual buds inhibited with the different indole acetic acid concentrations are compared with those of the control buds treated with pure lanoline, the points will practically coincide by changing only the time axis (see fig. 3). This means that for several days (two to four, or more) the buds were completely inhibited and that the inhibition was then almost instantaneously and completely released. It even seems that the initial growth of the buds was slightly more rapid when they had first been inhibited. The supply of auxin from the lanoline paste at the cut surface was more or less continuous, and only gradually it decreased, so that this phenomenon of sudden release of inhibition cannot be explained by a sudden change in auxin concentration. Besides, this release of inhibition occurred sooner the closer the bud was to the auxin supply. In figures 1 and 2 the ultimate growth rate of the inhibited buds does not seem to parallel the growth rate of the controls, but this is due to the fact that not all inhibited buds started to grow simultaneously, and some were still dormant at the time of the last growth measurement.

The effect of distance on bud inhibition was also studied with other compounds, which were not so effective in growth or even had no growth activity at all, but which gave the preparatory reaction in the pea test (hemi-auxins). Thimann (1935) had already reported that substances able to cause growth but deficient in transportability (indene acetic acid and coumaryl acetic acid) caused strong bud inhibition when applied close (7-9 mm.) to the bud but had little effect when applied

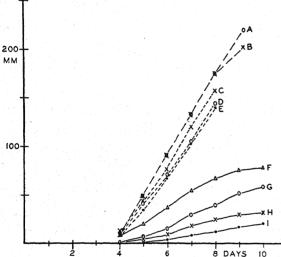

Fig. 1 (above). Relation between bud length (ordinate) and time (abscissa) after decapitation and application of pure lanoline (A), indole acetic acid 0.2 mg/g lanoline (B, C, D), and 1 mg/g (E, F, G, H). Decapitated 5 mm. (B, E), 15 mm. (B, F), 30 mm. (A, C, G), and 50 mm. above bud (D, H).

Fig. 2 (below). Relation between bud length (ordinate) and time (abscissa) after decapitation and application of pure lanoline (C, D, E), indole acetic acid 0.05 mg/g lanoline (A, B), and 0.2 mg/g (F, G, H, I). Decapitated 5 mm. (A, F), 15 mm. (A, D, G), 30 mm. (B, C, H), or 50 mm. (B, E, I) above bud.

50-60 mm. above the bud. And Van Overbeek (1938) found the same thing for  $\gamma$  phenyl butyric acid, a hemi-auxin. The experiments carried out by the writer on many thousands of peas were too variable to present all data in detail, but table 1 summarizes the results. Lower concentrations of all these substances had no effect, with hydrocinnamic acid no inhibition was found at 4 mg/g and lower, benzoic acid was inactive in 4 mg/g. In all

Table 1. Decrease of bud inhibition when different concentrations of substances are applied at various distances from the bud.

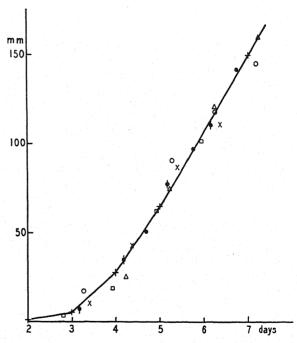

Fig. 3. Growth of lateral buds (ordinate: length; abscissa: days after decapitation) on decapitated shoots treated with pure lanoline (drawn line, same data as fig. 1, curve A). Over this line are fitted by shifting along the abscissa, the growth curves of lateral buds which were inhibited for 2–5 days by indole acetic acid pastes. Each dot, triangle, circle, etc., is the mean of several buds which started to grow at the same time. Triangle and cross come from plants of curve F, squares from curve E, dots from curve D, and circles from curve E on figure 1.

111

cases in which inhibition was only partial, some buds grew at a normal rate, whereas others were strongly inhibited. As far as could be determined, this was not due to a lack of contact between paste and the apical cut surface.

In this connection some other experiments have to be mentioned. When cis cinnamic acid 10 mg/g or phenyl butyric acid 10 mg/g were applied 5 mm. above the third node, the bud on this node was strongly inhibited. But soon the bud on the second node started to grow out, and then the higher bud was inhibited from two sides. What happened to the auxin coming from the upper bud that it did not inhibit the lower one? This is partially answered in an experiment, reproduced in table 2, in

Table 2. Auxin content by ether extraction, in degrees Avena curvature (with standard deviation), of buds and 30 mm. of stem of pea plants 56 hours after decapitation.

Decapitated stems treated 56 hours with	Stem	Bud	Total
Lanoline Indole acetic acid	$9.5 \pm 0.7$	$9.8 \pm 0.8$	19.3 ± 1.1
0.05 mg/g Phenyl butyric acid	$10.8 \pm 1.0$	$10.7 \pm 0.9$	$21.5 \pm 1.3$
2 mg/g	$6.5\pm0.6$	$15.5\pm1.1$	$22.0 \pm 1.2$

which the bud and 30 mm. of adjoining stem were analyzed for auxin by extracting them with ether. It will be seen that lanoline and a low applied auxin concentration gave the same amount of auxin. But although the total amount of auxin present in the plants inhibited with phenyl butyric acid was the same, its distribution was different, since more was present in the bud and less in the stem. This is an indication that less auxin was transported downward, and thus the inhibition of the lower bud through the upper would be smaller. The same decrease in auxin content of the stems treated with

phenyl butyric acid was found by Van Overbeek (1938).

RELATION BETWEEN AUXIN AND BUD GROWTH FAC-TORS .- In order to find out something more about the relation between the inhibiting substances and the bud growth factors, another technique was used in the following experiments. Pea stems were decapitated at a certain distance above the bud whose growth was to be studied. Then lanoline containing various concentrations of indole acetic acid or y phenyl butyric acid was applied to the cut surface and left for periods ranging from 24-48 hours. Then the extreme apex with the lanoline paste was removed, the stems were cut 3 cm. below the bud and placed in vials containing 1 cc. of a 2 per cent sucrose solution. In the next few days the buds started to grow out, but very soon they had exhausted the supply of bud growth factors, and growth stopped. Measuring of the bud length after 5-7 days allowed the approximate determination of the amount of bud growth factors which were present in the piece of stem at the moment of placing the stem with bud in the sugar solution.

When pieces of stem were cut off immediately after decapitation, practically no bud growth occurred. On some days this residual growth was somewhat more than on others. But when the peas were left decapitated for one or two days, the buds not only started to grow out, but also showed considerable further growth when the stems were cut off and placed in sugar solution. (See table 3.) When the peas were cut immediately after decapitation, the buds did not become visible and measurable in this experiment. But from then on each 12 hours longer they were left on the plant practically doubled their ultimate length. This was not due to the difference in initial length, since between the 12 and the 48 hour group there was at most a 0.5 mm. difference in bud length at the moment the stems were cut off. It was due rather to a greater growth response.

Table 3. Length of buds in mm. on isolated pieces of etiolated pea stems, 2, 4, and 7 days after cutting them off 30 mm. below the bud and placing them in 2 per cent sucrose. The peas were decapitated 10 mm. above the bud 12, 24, 36, 48, or 60 hours before cutting them off. Immediately after decapitation, paste was applied. Each figure represents the mean length of 15-80 buds.

WENT-BUD GROWTH

Indole acetic acid 0.05 mg/g	1.0	5.8	7.4	8.2		1.0	2.5	3.1	4.0
Indole acetic acid 0.2 mg/g		2.9	3.1	3.7		0.9	1.6	2.1	2.7
Indole acetic acid 1 mg/g	0	0	0.3	0.3		0.1	0.4	0.6	0.7
Phenyl butyric acid 2 mg/g	1.0	5.0	7.6	8.7		1.0	2.0	2.5	2.7

The ultimate cessation of growth was not due to a lack of carbohydrates nor to an auxin shortage, since application of a very low concentration of indole acetic acid (0.02 mg/g lanoline), which in intact plants would not appreciably affect growth, slightly inhibited the bud growth when applied to the apical cut surface of isolated stems (in 3 groups 5.4, 5.0 and 4.2 mm. against 7.6, 7.6 and 7.3 mm.). Neither did application of 100 or 10 mg. tryptamine per liter 2 per cent sucrose solution increase bud growth.

Table 4 gives the data of an experiment which was planned to determine what auxin application actually does to the bud growth factors. Peas were decapitated 20 mm. above the bud, and paste was applied. Forty-eight hours later the paste was removed and the stems all cut 30 mm. below the bud. The stems of one-half the group were cut off immediately above the bud. Then they were

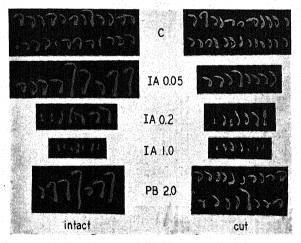

Fig. 4. Length of lateral buds one day after the last measurement of table 4. Pea stems decapitated 20 mm. above lower lateral bud and lanoline paste applied; C = pure lanoline, IA = indole acetic acid, 0.05, 0.2, and 1.0 mg/g lanoline, PB = phenyl butyric acid 2 mg/g. Two days later all stems were cut 30 mm. below lower bud. Those marked "intact" had only the paste removed from the stem apex (column A, table 4), from those marked "cut" the stem above the bud was cut off (column B, table 4).

placed in small vials in a 2 per cent sucrose solution. At that time no difference in the development of the buds could be noticed, except with the highest indole acetic acid concentration, which so completely inhibited the buds that they were not visible between the bracts.

There is a remarkable difference between groups A and B (see also fig. 4). When the 20 mm. piece of stem which was left after decapitation was cut off before the buds started to grow, the buds grew considerably less than when it was left on, which means that this piece contained a considerable amount of bud growth factors. And it contained much more of these when the tops had been treated with y phenyl butyric acid or a low indole acetic acid concentration than the lanoline controls. Further, an auxin concentration which caused a considerable bud inhibition (0.2 mg/g; see fig. 1, 2) did not have such an effect when the paste was removed after two days. Figure 4, which gives a clear picture of this experiment, shows the shadow picture of the buds six days after cutting the stems off.

In another experiment of the same type the buds were weighed. The stem was decapitated 10 mm. above the bud, and two days later cut 30 mm. below and immediately above the bud. Eight days later the weight per bud was:

Lanoline control 2.9 mg	2.9 mg
Indole acetic acid 0.05 mg/g	3.6 mg
Indole acetic acid 0.2 mg/g	
Indole acetic acid 1 mg/g	
Phenyl butyric acid 2 mg/g	5.3 mg
Phenyl butyric acid 5 mg/g	$4.0  \mathrm{mg}$

In this experiment the buds grew out to 0.7 mg. only when the stems were cut immediately after decapitation.

Because of the importance of these experiments in discussing the problem of bud inhibition, still another experiment is presented in table 5.

The results closely parallel those of table 4. In another experiment the effect of phenyl butyric acid 2 mg/g of increasing subsequent bud growth was found only when the stems were decapitated 7 mm. above the bud, but not with 20 mm., as was found in the experiment of table 4.

Table 5. For explanation see table 4.

Decapitation	5	mm. al	bove bu	d	20 mm. above bud			
After 48 hours	Cut above		Not	cut		just e bud	Not	cut
Measured after days	2	6	2	6	2	6	2	6
Lanoline control	1.6	1.7	1.1	1.4	1.2	1.4	1.9	2.3
Indole acetic acid 0.02 mg/g	1.5	1.6	1.4	1.8	1.4	1.4	2.6	3.4
Indole acetic acid 0.05 mg/g	1.2	1.3	1.1	1.3	1.4	1.5	3.0	3.7
Indole acetic acid 0.10 mg/g		1.1	0.7	1.0	1.7	1.9	2.2	2.6
Indole acetic acid 1.0 mg/g		0.4	0.2	0.2	0.2	0.2	0	0

In the experiment of table 3 also data on the optimum indole acetic acid concentration were obtained. When treated with pure lanoline the bud length was  $2.8\,\pm\,0.17$  mm.

With indole acetic acid 0.014 mg/g

bud length was 3.0 mm.

With indole acetic acid 0.02 mg/g

bud length was 3.4

With indole acetic acid 0.033 mg/g bud length was 3.5  $\pm$  0.21 mm.

With indole acetic acid 0.05 mg/g

bud length was 3.2 mm.

With indole acetic acid 0.1 mg/g

bud length was 1.8 mm.

From these figures an optimum concentration of 0.03 mg. per gram lanoline can be calculated; table 4 indicates 0.05 mg/g. The difference between these figures is not very large, and the most important point is that in each case there was a considerable increase in bud length when the peas were pre-treated with low auxin concentration, provided that 5-20 mm. of stem was left above the bud. The fact that when this part of the stem above the bud was cut off no appreciable increase in bud growth occurred indicates that a difference in length of the bud at the moment of cutting of the stem was not responsible for the increased growth later, of which effect the 0 hour measurements of table 4 give a direct proof. Furthermore,

when the growth rate for equal bud lengths was calculated, it was always greater for the auxin treated stems than for the controls.

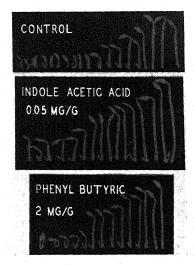

Fig. 5. Lateral buds developed on pea stems, cut off 30 mm. below the bud two days after decapitation 10 mm. above this bud. Lanoline pastes were applied to the apical cut surface during these two days. Measurements of these buds two days earlier are recorded in the last column of table 6.

Table 6. Each figure is the mean length in mm. or weight in mg. of 8-10 lateral buds 5 days after decapitation. The peas were decapitated 10 mm. above the second (lower bud) or third (upper bud) internode, and lanoline paste was applied to the cut surface. One or two days later the paste was removed by cutting off the extreme 2 mm. of the stem, the stems were cut 30 mm. below the bud (lower or upper) and placed in 2 per cent sucrose solution.

	Cut off 1	lay after decapitation	Cut off 2 da	ays after decapitation
	Lower bud	Upper bud	Lower bud	Upper bud

below bud	0.02	3.3	8.8		10.1	5.5
	0.05	2.3	6.1		6.2	3.8

The magnitude of this effect of auxin on the distribution of bud growth factors varies from experiment to experiment. In only one experiment was the effect so small that it might be questioned. In all other experiments (seven, each comprising 200–450 plants) an effect was clearly noticed. In the sixth experiment the increase in bud growth by a previous treatment with 0.05 mg/indole acetic acid per gram lanoline was statistically highly significant (see table 6 and fig. 5), the difference between treated and control plants being more than three times the standard deviation.

In another experiment the determinations described above were combined with direct measurements of bud inhibition when the stems were not cut off at the base. As table 7 shows, an indole acetic acid concentration which caused bud inhibition as long as the stems were attached to the plant had very definitely increased the amount of available bud growth factors in those stems. Thus the simultaneous occurrence of bud inhibition and accumulation of bud growth factors was proven.

Lower shoots inhibiting more apical shoots. -The following observations are of interest in connection with the fact that in decapitated peas the most apical bud grows out when the cotyledons are present, but when the cotyledons are cut, the basal or even cotyledonary buds will develop (Went, 1938a). When a pea stem is cut off, it will not grow any more, nor will lateral buds develop, until a functional connection with a new root system has This can be done either by been established. grafting the stems on another root system or by letting adventitious roots develop. In the latter case the amount of storage food seems to be inadequate to cause much growth, and only when a leaf is present and the plants are exposed to light does much bud growth take place. But when the shoots are grafted, and a graft union is established, the apical and lateral buds can renew growth (Went, 1938b). If before the formation of the graft union lateral buds below the graft start to grow out, they completely inhibit growth of the grafted shoot. But one or two days after cutting off these laterals the grafted shoot will grow at a normal rate and then

inhibit the lower lateral buds. Thus we have a perfect case of correlative inhibition which is carried from base to top, such as Snow (1931b) has demonstrated to exist; and in the same stems an inhibition could be carried from top to base.

A more remarkable fact was observed in these grafting experiments. If the grafted shoot was rather long (50 mm. or over), and if a lateral bud was present near its basal cut surface, in some cases this bud did grow out after the graft had "taken," and in that case the apical bud was completely inhibited. From the measurements it appeared that sometimes the apical bud started to grow (very slowly) simultaneously with the lateral bud and very soon was completely inhibited by the growing lateral bud, but in other cases the lateral bud inhibited the apical from the beginning. This inhibition was not due to injury of the apical bud or inability to grow, for as soon as the lateral was removed, the apical bud resumed growth. In none of these experiments were indications of injury due to the inhibition by more basal growing buds observed, such as Snow describes (1931b). This may be due to the difference in method (Snow grew his plants in daylight) or the shorter time in the experiments reported above.

BUD GROWTH AND BUD INHIBITION ON ROOTS.—It was thought that more information about bud growth might be gathered from experiments with roots which regenerate buds on their basal cut surface. Many such roots are known (Cichorium, Cakile, Taraxacum), but the following preliminary experiments were performed with the fleshy roots of Oenothera macrosiphon. These plants were suggested for the experiments by Dr. S. H. Emerson, who had observed the abundant formation of adventitious shoots whenever a basal cut surface of these roots was exposed. The roots of a few plants were carefully washed, cut into pieces 8 cm. long, and combined into comparable groups of five pieces each. In general the very thick and the thinner (more apical) parts of the roots gave similar response.

The roots were left at 24°C. and 85 per cent humidity in a dark room, each one individually apex

Table 8. Number, total length, and total weight of the shoots, developed in 14 days on the basal cut surface of five pieces of Oenothera macrosiphon roots 8 cm. long. They were first treated for 5 days with indole acetic acid. Root formation: 1 very poor, 2 poor, 3 good, 4 very heavy.

0						1,120 mm.	2,118 mg.	3

down in a small bottle 6 cm. high, with a small amount of water. The indole acetic acid was supplied by immersing the extreme tip of apical or basal cut surface in the solution for from one to five days. Afterwards the base was cut or left intact. Two weeks later the shoot and root development was noted (see table 8). The following conclusions may be drawn:

The number of shoots developing is less when the basal side was immersed in the solution. Apparently this had a toxic effect. Renewing the cut surface did away with this inhibition.

When treated with indole acetic acid, the number of adventitious shoots developing was not greatly affected; their total length and weight, however, dropped off very much when treated with the higher indole acetic acid concentrations. This means that the treatment primarily affected the bud growth factors and not the initiation of buds.

Apical treatment of the roots with indole acetic acid increased only their root formation, but had little effect on bud development.

There seemed to be a more or less inverse relationship between root and shoot development on these root cuttings.

In another experiment basal treatment with high indole acetic acid concentration even caused roots to grow out from the base on two out of eight cuttings, whereas the bud formation was completely inhibited.

Discussion.—The facts presented in this paper form a good basis for discussion of some of the bud inhibition theories put forward by different investigators. Any theory trying to explain bud inhibition by a direct effect of auxin (Thimann, 1937) is at a loss to explain the increase of inhibition with distance. For on the one hand the inhibition is the more complete the higher the applied auxin concentration; on the other hand the inhibition becomes

stronger the farther away the buds are located from the place of application. For Snow's theory of a specific inhibitor formed under the influence of auxin this effect of distance gives no difficulties except that it has to be assumed that everywhere in the stem the inhibitor is formed with the transporting auxin. However, some substances which definitely do not cause growth (\gamma\ phenyl butyric acid) can inhibit buds, and therefore Snow's hypothesis (1937) would have to be modified. The diversion hypothesis (Went, 1936), which assumes that an apical supply of auxin causes the other bud growth factors (like caulocaline (Went, 1938a)) to move towards this supply, does not depend on the growth activity of substances for its validity. And the increase of inhibition with distance follows directly from the assumption made. For the effect of applied auxin would be to cause more and more caulocaline to accumulate in the upper part of the decapitated stem. This might be compared with the filling of a tube. As soon as the tube is full as far as the bud, it will overflow into the bud, and from then on the bud starts to grow at a normal rate. This overflow principle explains in the first place why there is an increase in inhibition with distance, since the longer the piece of stem to be filled up, the longer it will take, and the more complete the inhibition is. And in the second place it gives a good reason for the sudden release of inhibition. The latter effect can be explained equally well with Van Overbeek's (1938) blocking hypothesis.

Another conclusion can be drawn from the experiments. A high auxin concentration inhibits a bud for a longer period than a low concentration. Since the growth after release of the inhibition is the same, the flow of bud growth factors to the lateral buds is the same with both a high and a low auxin concentration. Therefore, the higher the applied auxin concentration, the higher the con-

centration of caulocaline can become in the portion of the stem between the bud and the auxin paste. Further experiments may disclose whether all or only part of the accumulated caulocaline can be recovered. In the growing apical bud the caulocaline is used in growth as soon as it arrives, and there are no indications that it accumulates. This may be the case only in dormant buds. Not enough facts are available to go deeper into this problem.

A very nice proof of the contention that under the influence of auxin, caulocaline, or bud growth factors in general, accumulate in the stem apical from the bud, is given in the experiments of tables 4, 5, 6 and 7. In these experiments a differentiation between two activities of auxin is made. In the first place a continuous supply of low concentration during the outgrowth of the bud decreases its growth. But on the other hand a pre-treatment with indole acetic acid greatly increases growth. If too high a concentration is applied, apparently enough remains in the piece of stem to inhibit further growth, but concentrations, causing inhibition when applied continuously, increase bud growth when the stem is treated for the first one or two days after decapitation. This fact is completely unexplainable on the basis of Snow's theory of the formation of a special inhibitor under the influence of the auxin action. The experiments seem simple enough, and are so completely reproducible as to be conclusive. Especially the experiment of table 7 is convincing, since the accumulation of bud growth factors is shown to occur under the influence of indole acetic acid, while in comparable plants the same concentration causes bud inhibition.

It seems that for these experiments the diversion hypothesis, among the existing theories, gives the only possible explanation. This hypothesis also furnishes a good explanation of the inhibition of higher lateral buds or even the apical bud by a rapidly growing lower lateral bud. This lower bud overtakes a more apical bud only when (a) the auxin supply from above is reduced, as in the grafting experiments, or (b) in the experiments in which the cotyledons are removed, or (c) when a substance which has only a limited transportability is applied. But once it has the lead, the apical bud does not have a chance as long as the basal bud is growing. The latter facts are difficult to explain on the basis of Van Overbeek's blocking hypothesis. For the vascular connections of the apical bud with the base of the plant are normally developed and, according to the hypothesis, could not be blocked for the transport of growth factors by auxin. Besides, very little auxin is present in these apical buds which are not growing.

A further discussion of bud inhibition theories does not seem necessary, with the review of Thimann (1939) at hand. A few words, however, might be added concerning the modification of Went's diversion hypothesis by Ferman (1938), who claims that not specific bud growth factors like

caulocaline, but the auxin precursor are diverted by the auxin, natural or applied. The data presented in table 2 and the fact that tryptamine, which can act as an auxin precursor (Skoog, 1937), has no effect on bud growth in excised pea stems are not in favor of Ferman's supposition. Also in other experiments with grafted peas no correlation between growth rate and auxin production was found (Went, 1938b) so that there neither the auxin nor the auxin precursor were the limiting factors for bud growth. Although the present author believes that not only calines but also the auxin precursor may be diverted under the influence of auxin (see e.g. Went, 1935), he does not believe that diversion of the auxin precursor underlies the phenomenon of bud inhibition. This is supported by the determinations of Van Overbeek (1938).

The experiments with bud growth on the Oenothera roots are interesting inasmuch as they show that the phenomenon of bud inhibition by auxin is the same in stems and roots. It does not primarily affect the initiation of shoots, but their subsequent growth. Another interesting fact is that the polarity in the auxin effect is very pronounced, which is noteworthy since hardly any polarity of auxin transport in roots was observed (Heidt, 1931; Gorter, 1932; Faber, 1936). It is quite clear that in this respect the polarity of the root is continuous with that of the shoot, as Went (1932) had postulated.

#### SUMMARY

In experiments with etiolated pea shoots the phenomenon of increasing inhibition with increasing distance between inhibited lateral bud and inhibiting agent (Snow, 1931a) is confirmed with application of indole acetic acid at different distances from the lateral bud. The inhibiting effect of some non-auxins and substances with low growth activity is described.

The most important experiments were carried out with short pieces of stem (30–50 mm. long), carrying one lateral bud. They were cut off the plant at various times after decapitation and application of various substances. The experiments show that the indole acetic acid and  $\gamma$  phenyl butyric acid caused an accumulation of bud growth factors just below their point of application and that they did not inhibit growth by themselves. The experiments show very clearly that the inhibition is a secondary effect of the applied auxin.

Some cases of inhibition of the apical bud by lateral buds are described.

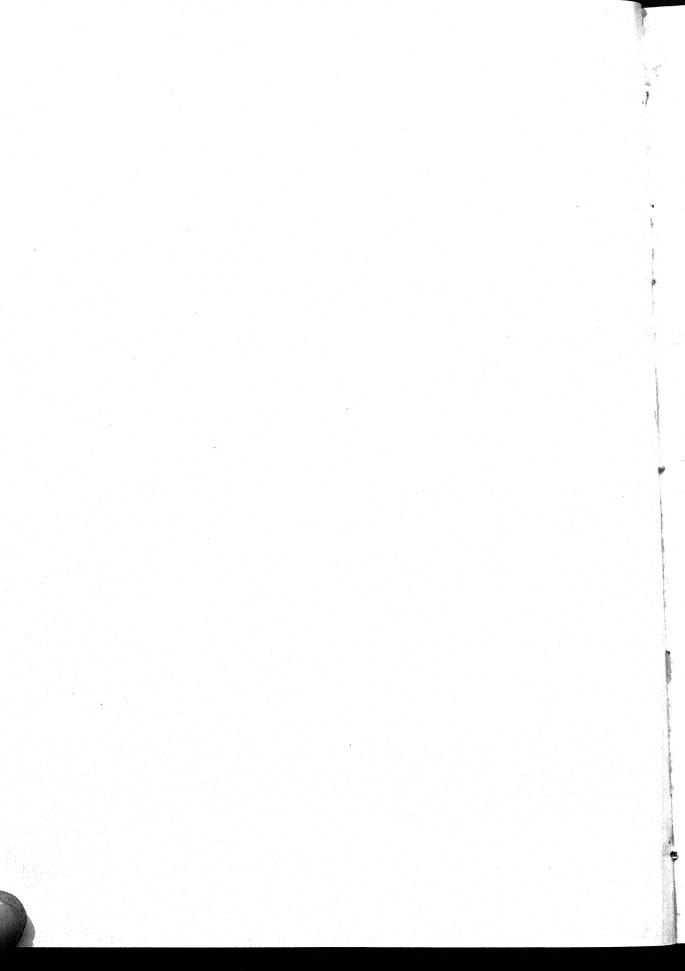

Finally, it is shown that bud inhibition can be brought about in roots which regenerate buds on their basal cut surface in much the same way that it can be brought about in stems.

## A NEW CONIDIOBOLUS WITH SEXUAL REPRODUCTION 1

John N. Couch

THE GENUS Conidiobolus was founded by Brefeld (1884) on C. utriculosus and C. minor, which were overgrowing the fruit bodies of certain jelly fungi. Both species were accidentally obtained while Brefeld was trying to get cultures of Hirneola and Exidia from spores by placing the fruit bodies over slides on which were drops of water and nutrient solutions. Such fruit bodies were placed under bell jars, and on the second day Brefeld discovered the large conidia-bearing mycelium growing on his slides and overrunning the germinating spores of the jelly fungi. At first Brefeld looked upon the fungus as an interloper and a pest, but later, upon seeing the peculiar Entomophthora-like conidia, he became interested, isolated the fungus, and kept it in culture in dung decoction for over six months, during which time his studies were made. Brefeld described in great detail the vegetative structure, conidial formation, and sexual reproduction in C. utriculosus. The sexual reproduction is of particular interest. Gametangia of unequal size conjugate, the zygote being formed in the swollen part of the larger cell.

Up to the present time, we know nothing of the sexuality of *Conidiobolus* except from Brefeld's original description of *C. utriculosus*. The chief object of this paper is to describe a species of *Conidiobolus* in which the same type of sexual reproduction occurs and to discuss the validity of the genus in the light of more recent researches.

The fungus described below appeared as a contaminant, May 13, 1935, in a Petri dish on maltosepeptone agar with spores shot from Septobasidium apiculatum on Cornus amomum. It is impossible to be certain what the fungus was growing on in nature, perhaps the Septobasidium or a small insect or perhaps (and this is very unlikely) the Conidiobolus was brought in by air currents from an unknown source.

Conidiobolus Brefeldianus sp. nov.—Mycelium thread-like or breaking into hyphal bodies, depending upon the culture media. On maltose-peptone agar No.  $5^2$  forming an intramatrical disc, the outer zone of hyphal ends being full of vacuolate protoplasm and alive, while the older hyphae are mostly dead and empty of protoplasm. Hyphae wavy or straight,  $5.4-8.4\,\mu$  thick, branched, septate, the cross wall usually thick and conspicuous, as a rule without constrictions at the septa; the segments, variable in length from about 50 to several hundred microns long, usually  $300-420\,\mu$ . Protoplasm with numerous conspicuous granules and rounded or elongated vacuoles. Conidiophores unbranched, positively phototrophic, stalk usually distinctly swollen in the middle, usually  $7-10\,\times\,30-50\,\mu$ , but sometimes much longer; each conidiophore giving rise

<sup>1</sup> Received for publication November 30, 1938. Presented before the Mycological Society of America,

Atlantic City, December, 1936.

to one conidium. Conidia spherical, 10-31  $\mu$  thick, mostly about 20  $\mu$  thick, with a conical apiculus about 7.5  $\mu$  wide at the base and 5-7.5  $\mu$  long on conidia of average size. Conidia forcibly discharged by the sudden out-pushing of the papilla. Columella cone-shaped, persistent. Sexual reproduction by the conjugation of spherical gametangia of unequal size which usually arise from the adjacent ends of two segments in the same thread, or sometimes from two parallel threads or from two branches of the same thread. Smaller gametangia 9-12.6  $\mu$  thick when mature. Zygote formed in larger gametangium, spherical, 18-33  $\mu$  thick, usually about 23  $\mu$  thick, with smooth, thick, three-layered (?) wall, and one large, conspicuous, eccentric oil (?) globule which is outside the protoplasm; capable of germinating after a rest period of two weeks or more.

Conidiobolus Brefeldianus.—Mycelio ramoso, septato, rare fragmentario; hyphis 4.2–10  $\mu$  latis, segmentis 50 usque ad aliquot centena  $\mu$  longis; conidiophoris erectis, positive phototropicis, 7–10  $\times$  30–50  $\mu$ , simplicibus, clavatis, solitario conidio in apice; conidiis globosis, hyalinis, levibus, 10–25  $\mu$  latis, distincta conica papilla, valide ejectis; sporis perdurantibus (zygosporis) e copulatione laterali vel scalariformi cellularum hypharum efformatis; zygosporis intra cellulam in qua plasmata se jungunt efformatis, globosis, 21–33  $\mu$  latis, excentrico guttulo et episporio levi hyalino maturitate.

This species may readily be distinguished from C. utriculosus Brefeld by structural differences and by its much smaller size throughout. In C. utriculosus the conidia are pear-shaped (Brefeld's figures are more nearly ovoid with a short papilla), smooth,  $35 \mu$  wide by  $50 \mu$  long; while the conidia in the present species are spherical, smooth, 10-31 µ thick, most about 20 µ thick. Also in C. utriculosus the zygotes are 60-100  $\mu$  thick, most about 80  $\mu$  thick, and are furnished with a minutely warted almost colorless or bright yellow wall, while in the present species the zygotes are  $20-33 \mu$  thick, most about  $23 \mu$  thick, and have smooth walls. Brefeld gives no measurements, but the mycelial threads in his species appear from his drawings to be larger than in the present one. Brefeld cultured his fungus only in dung decoction, and it is possible that the numerous, short, lateral out-pocketings as well as the absence of septations in the young mycelium were due to the culture conditions. Brefeld's second species, C. minor, is based on a few small conidia observed in cultures of C. utriculosus. Martin (1925) suggests that these conidia were doubtless small ones of C. utriculosus reduced in size by repeated germinations in old cultures.

EXPERIMENTS WITH VARIOUS CULTURE MEDIA.—Considerable experimenting has been done to determine the different types of food substance utilized by Conidiobolus Brefeldianus and the character of growth of the fungus on different substrata. Only the more significant results are here summarized.

 $<sup>^2</sup>$  1,000 cc. H2O, 20 grams agar, 3 grams maltose, 1 gram meat peptone.

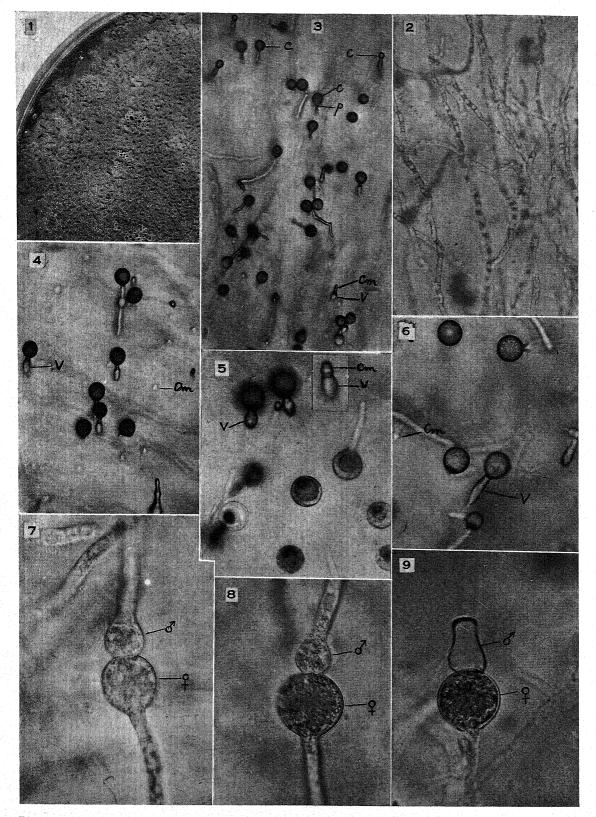

Fig. 1-9.—Fig. 1. Showing convoluted growth on sterilized egg yolk. Slightly enlarged.—Fig. 2. Mycelium on agar No. 35. Note vacuolate cytoplasm. A few septa are visible. Dark spots are conidia out of focus. Threads are all within agar. ×150.—Fig. 3. Conidiophores of different ages grown in dark chamber with small side opening.

The fungus will grow on a wide range of vegetable and animal matter. On cooked vegetables, such as carrots or sweet potatoes, growth is luxuriant, while on raw vegetables it is very poor. No growth occurred on cooked or raw fruits or fruit juices such as Winesap apples, Concord grapes, and Crataegus fruits. Growth on sterilized egg yolk (fig. 1) resembles the type of growth shown by Sawyer (1929, fig. 5) for Empusa sp. and thus tends to emphasize the physiological relationship between Conidiobolus Brefeldianus and Empusa sp. On the other hand, C. Brefeldianus failed to grow on any of the sterilized meats such as veal, pork, or lean beef, while Sawyer (1929) was able to culture Empusa sp. on such substrata. In horse dung decoctions of varying strengths our fungus produced fair growth. The threads were straight without the outpocketings described by Brefeld as very characteristic of C. utriculosus in the same media. Furthermore, in this culture medium our fungus produced very few conidia and no zygotes, while in the same culture medium such structures were abundantly formed in C. utriculosus. The conidial types on raw egg albumen are worthy of mention. On this medium many secondary conidiophores and conidia were formed. In some instances the primary conidium gave rise to a number of short stalks, on each of which was borne a small conidium (fig. 25, 26, 29), thus resembling the secondary conidiophores of Delacroixia coronata as described by Costantin (1897), Gallaud (1905), and Kevorkian (1937). Frequently the primary conidium gave rise to a long secondary conidiophore bearing on the swollen end 3 to 7 small conidia, each on a short, slender stalk, the structure strikingly resembling a basidium (fig.

In experiments with living insects one individual of an unidentified species of small hymenopterous wasp was infected, and also several gnats. Another species of hymenopterous wasp was uninfected after being in contact with the fungus for several days. Fruit flies (Drosophila melanogaster) on slices of bananas in contact with the fungus were uninfected and perfectly healthy after two weeks. The fungus also failed to infect termites, the latter making tunnels in the agar and living for several days until the cultures were overgrown by Penicillium.

Conidial formation.—Given a healthy mycelium on a favorable culture medium, the formation of conidia seems to be determined by proper aeration, a condition corroborated by Berdan (1937, 1938) in this laboratory for several species of Ancylistes.

Conidia are formed only if part of the mycelium is at the surface. On agar the threads at or close to the surface give rise to most of the conidiophores, but in such a culture conidiophores may also arise from threads deep within the agar. On the other hand, if the culture is entirely submerged in liquid media, no conidiophores are formed. However, if such a culture is supported at the surface, conidiophores are formed in about an hour's time.

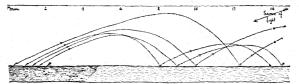

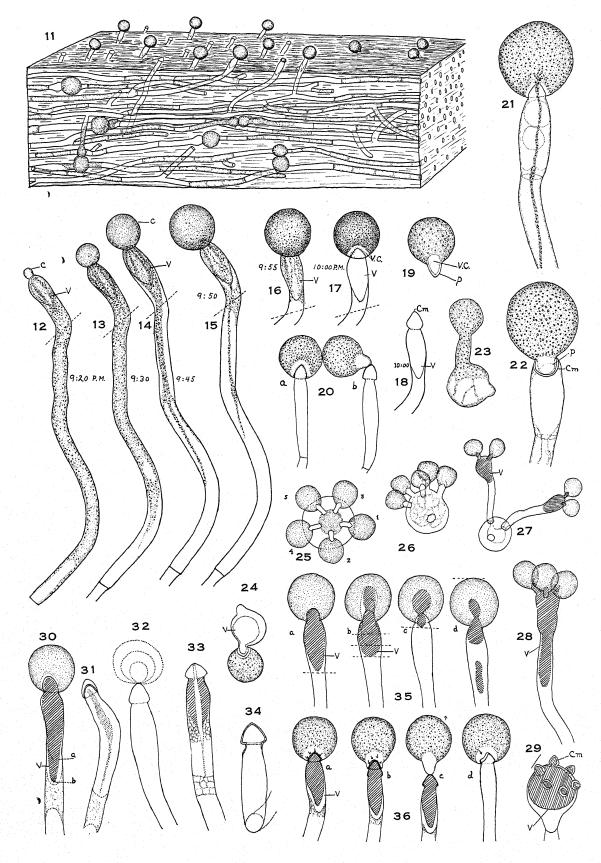

Fig. 10. Diagrammatic representation of the discharge of conidia on an agar plate, darkened save for one small source of lateral illumination. The direction from which the light comes is indicated by an arrow. The conidia, when discharged, may form secondary conidiophores, the secondary conidia being discharged again, and thus the conidia march across the plate toward the light. As indicated by the scale of millimeters, the conidia travel from 5 to 12 millimeters with each discharge. × about 100.

At first it seemed evident that the formation of the conidiophores was determined by light.3 In the first place, when cultures are kept out in the room and thus subjected to alternating daylight and darkness, they show a distinct concentric zonation, a new zone being formed each twenty-four hours; and in the second place, the conidiophores are positively phototropic. It has been found, however, that the formation of conidia is determined primarily by the nutrient material and only secondarily by light, thus corroborating the work of Lendner (1897). However, the number of conidia finally formed in alternating daylight and darkness is several times greater than in either continuous darkness or continuous light. Although conidia are formed on a great variety of culture media, certain media are far more favorable for their formation than others, as, for example, potato dextrose agar and a modification of Blakeslee's "230" in which the sugars are reduced by half (2 per cent agar, 1 per cent glucose, 1 per cent dextrose, 0.1 per cent peptone), whereas on agar No. 35 (see below for formula) practically no conidia are formed in total darkness and only a few in alternating darkness and

<sup>3</sup> The writer is indebted to Mr. George Christenberry for help with some of the experiments on the effect of light.

Conidiophores all directed toward source of light. ×150.—Fig. 4. Another region from same culture showing positive phototrophism of conidiophores. Note whitish columellae of old conidiophores and collapsed stalks. ×200.—Fig. 5. Note two conidiophores at top left each with a conspicuous vacuole in stalk. ×512. Small insert to right of two conidiophores shows columella and vacuole just after conidium had been shot. ×700. Also note germinating conidium and dark areas (vacuoles) in conidia toward middle and lower part of figure.—Fig. 6. Conidia, the large one at top right with collapsed stalk, the one just below middle with rigid stalk. Note collapsed conidiophore with conspicuous whitish columella on extreme left of figure. Young conidiophore on extreme right center before conidium has appeared. ×400.—Fig. 7-9. Stages in formation of zygote, smaller gametangium above larger below. In figure 9 small gametangium has completely emptied into larger. ×700.

light. In general it appears that media rich in carbohydrates favor the formation of conidia, while media rich (but not too rich) in peptone favor the formation of zygotes.

Under optimum conditions the formation of conidia may proceed very rapidly, the entire process from the upward growth of the conidiophore to the final ejection of the conidium occupying from 50 minutes to two hours. Any segment close to the surface or deep in the agar except one destined for sexual reproduction may produce a conidiophore. The first indication that a segment is to produce a conidium is the growth of one of the ends, or of a lateral branch up to and slightly beyond the surface. The projecting part may be considered the conidiophore and not infrequently may be separated from the basal part by a cross wall. The protoplasm flows into the conidiophore, which enlarges into a club-shaped structure. The conidium itself arises as a bud from the tip of the conidiophore (fig. 3, 12).

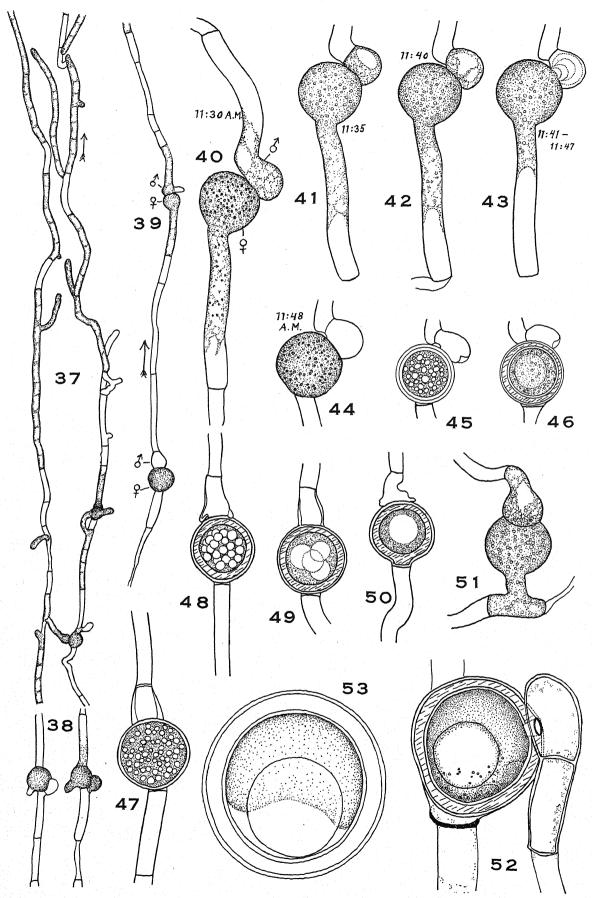

At an early stage in development a large, elongate, ovoid vacuole appears in the distal part of the conidiophore (fig. 5, 12). This structure is stained a yellowish orange with neutral red (1 part in 1,000  $\rm H_2O$ ) and extends up into the columella, persisting until the conidium is discharged and the conidiophore collapses (fig. 5, 6, 18, 30).

The protoplasm seems to flow up around the vacuole to pass into the conidium (fig. 12-16).

The movement of the protoplasm is fast enough so that one can easily observe the flow. As the conidium increases in size, the vacuole also enlarges. In figure 12 the conidium appeared as a minute bud at 9:20 p.m., and forty minutes later all the protoplasm had moved up into it (fig. 17).

After the conidiophore has become practically empty of its protoplasm, the vacuole stands out with striking clarity (fig. 5, 17, etc.). The nature of this vacuole is very puzzling. It is evident only when the conidiophore is in the air, having a greenish opaque appearance. If the surface of the agar is flooded with water, the vacuole disappears, and though the water is removed immediately, the conidium is not discharged (fig. 21, 22). That this vacuole is not an optical illusion may be strikingly demonstrated by applying a 1 per cent solution of chromic acid to the surface of the agar. If this is done slowly, one may observe that the vacuole becomes discolored and may be forced up into the conidium by the addition of more and more acid. If the conidium is also flooded by the acid, the vacuole may be forced back into the stalk (fig. 35, a-d). It is of interest to note that the vacuole in the conidiophore stalk takes a distinctly different color with neutral red from those in the threads or conidia. In the conidiophore the vacuole becomes vellowish-orange with neutral red, while the other vacuoles are red.

Fig. 11-36.—Fig. 11. Semidiagrammatic surface and section view of small area of fungus on agar showing mycelium within agar, conidiophores some with conidia ready to be discharged, and others from which conidia have been ejected. Light comes from upper right. Note gametangia and two zygotes in agar also three conidia on surface of agar. X about 160.—Fig. 12-18. Successive stages in development and discharge of conidium. c, conidium; v, vacuole; vc, vacuole in conidium; cm, columella. Conidium (c) first appeared as a bud (fig. 12, c) 9:20 p.m. and was discharged fifty minutes later. Dotted line represents surface of agar. ×525.—Fig. 19. Mature conidium just after discharge. Note vacuole in papilla. ×525.—Fig. 20. Conidiophore just before and after discharge of conidium. Note vacuole in base of conidium in a and same vacuole in papilla in b. Conidium remained attached to columella. ×325.—Fig. 21. Conidiophore mounted in water showing strand of protoplasm flowing into conidium through tip of columella. Note large single vacuole has apparently been broken up into several smaller ones. ×930.—Fig. 22. Same conidiophore as above. After protoplasm had flowed into conidium, papilla evaginated, forcing columella to turn backwards into conidiophore. ×930.—Fig. 23, 24. Conidiophores germinating to form secondary conidia, the first with, the second without the stalk.  $\times 325$ .—Fig. 25, 26. Two conidia germinating on unsterilized egg albumen both of which have formed five secondary conidiophores. Vacuoles not shown. Small numbers, 1-5, in fig. 25 show order in which conidia were discharged.  $\times 525$ .—Fig. 27. Conidium with two basidialike conidiophores. On egg albumen. Note vacuoles. X335.—Fig. 28. Conidiophore with three secondary conidia. ×525.—Fig. 29. Conidium as shown in fig. 25, 26 after secondary conidia have been discharged showing six columellae with vacuole extending into each. Note hyaline cytoplasm delimiting vacuole.  $\times 525$ .—Fig. 31. Same conidiophore as above showing collapse of vacuole and loss of rigidity of stalk.  $\times 525$ .—Fig. 32. Conidiophore stalk of *C. villosus* immediately after spore discharge. Opening in columella failed to close normally and vacuolar fluid was extruded in a drop as indicated by dotted circles. ×220.—Fig. 33. Conidiophore stalk of C. Brefeldianus immediately after discharge of conidium showing opening in columella which had apparently failed to close; apparent channel through vacuolar substance, and disintegrating vacuolated cytoplasm. ×525.—Fig. 34. Section of columella showing thickened wall. ×930.—Fig. 35. a, b, c, d. Diagrams showing how content of vacuole may be forced into conidium by adding chrom-acetic solution (Claussen's fluid) to surface of agar. Dotted lines indicate height of acid solution. As more acid was added, b, vacuole was forced up into conidium, c. When entire conidiophore (d) was submerged in acid by adding cover slip, vacuole now in two parts and with a greenish cast emerged from conidium back into stalk. ×525.—Fig. 36. a, b, c. Show diagrammatically how conidium throws itself off by sudden evagination of papilla. This apparently is caused by increased pressure in vacuole of conidium. The vacuole in stalk keeps conidiophore rigid. d shows what happens when vacuole in stalk is plasmolized by addition of film of water to surface of agar. The vacuole in conidium having no rigid opposing force now pushes the papilla and columella back into stalk, and conidium fails to throw itself off.  $\times$ 525.

After all or nearly all the protoplasm has passed into the conidium, the columella is formed. This begins to form on the side and progresses centrifugally, finally forming a dome-shaped structure which projects into the conidium. Sometimes the colummella begins to form before all the protoplasm enters the conidium. In figure 21 the columella is completely formed except for a pore at the top through which protoplasm is continuing to stream. After this long strand of protoplasm had passed in, the pore in the columella was closed. A few minutes after the columella is formed, another membrane is laid down over it. This will become the wall of the papilla of the conidium.

About ten minutes after all the protoplasm has passed into the conidium, it is shot away. Several minutes before this occurs, a dome-shaped vacuole is formed over the columella (fig. 17, 20a). This vacuole increases in size, doubtless due to the absorption of liquid through the conidiophore (fig. 36a, b, c). The strong pressure within the spore created by this vacuole counterbalanced by the vacuole in the stalk (one can easily observe the increase in size of the vacuole in the stalk just before the conidium is discharged) brings about the annular rupture of the wall of the spore at the base of the columella. The instant this rupture occurs the papilla reverses its position with such violence that the spore is hurled through the air for 5 to 12 mm. (fig. 10). My observations agree essentially with those of Gallaud (1905) and Martin (1925), though neither of these authors emphasized sufficiently the rôle played by the columella, stalk, and vacuole in spore discharge. Before the spore is discharged, the columella wall becomes much thickened, and this reinforced wall normally prevents the columella from being pushed back into the stalk. Indeed, if a conidiophore is flooded with water shortly before the spore is ready to be discharged. the pressure within the spore may become so great that the columella is forced back into the stalk (fig. 22; see also Gallaud, 1905). The vacuole within the stalk plays an equally important rôle in that it furnishes the turgor pressure to keep the conidiophore rigid and thus furnishes the conidium an opposing force against which it may kick itself off.

If a culture is left upright on the table with uniform illumination from all sides, the conidia are shot out irregularly in all directions. But if a culture is illuminated more strongly on one side or, better, if it is put in a black box or other dark container with a small hole on one side to permit the entrance of light, the conidiophores will point toward the source of light, and the conidia will be shot in that direction (fig. 3, 4, 10, 11). The conidia may be hurled horizontally a maximum distance of 12 mm. or vertically 8 mm. (fig. 10).

If conditions are unfavorable for germination, a conidium may form a secondary conidium usually without a stalk (fig. 23, 24). This secondary conidium is shot away in the same manner toward the source of light. A third one may form and be shot away and so on until the conidium germinates or dies. By such behavior the protoplasm in one and the same conidium may travel across a plain agar plate (i.e., agar without nutrients) in a few hours' time.

Sexual reproduction.—The present fungus is capable of forming zygospores on a variety of culture media. The most favorable solid culture medium of a large number tried was agar No. 35 (1 liter  $\rm H_2O$ , 20 grams agar, 3 grams maltose, 4 grams meat peptone) on which the production of zygospores was very abundant, the number varying between 200 and 300 in the lower power field of view. A reduction or an increase in this amount of peptone caused a decrease in the production of zygospores. A very few zygospores are formed on plain agar.

Fig. 37-53.—Fig. 37. Threads on agar culture (agar no. 5) showing empty segments, segments with cytoplasm (note vacuoles), and lateral and scalariform conjugation. ×213.—Fig. 38. Male and female gametangia conjugating. In figure to right male cell resembling antheridium has been cut off; in figure to left male cell has emptied into larger. ×213.—Fig. 39. Thread showing young zygote below and gametangia about ready to conjugate above. Note how empty part of male segment is separated from protoplast as the latter moves toward female cell. ×213.—Fig. 40-46. Stages in conjugation of gametangia.—Fig. 40. 11:30 a.m., May 23. Both gametangia have reached mature size, and the protoplasm is flowing from the suspensors into the gametangia. ×787.—Fig. 41. 11:35 a.m., May 23. Smaller gametangium has been separated from suspensor by cross wall which is now straight in section view. Note vacuole in smaller gametangium. ×787.—Fig. 42. 11:40 a.m., May 23. Basal wall of smaller gametangium has become convex outwards, indicating internal pressure. Note vacuole and concentration of hyaline cytoplasm on wall between two gametangia. ×787.—Fig. 43. 11:41-11:47 a.m., May 23. Protoplasm of smaller gametangium began flowing into larger about 11:40, and by 11:47 the smaller was entirely empty. The dotted lines represent the successive positions of the plasma membrane at intervals of slightly more than a minute. ×787.-Fig. 44. 11:48 a.m., May 23. Suspensor of larger gametangium has become empty, and wall has formed, separating larger gametangium from its suspensor. For a few minutes after the smaller gametangium had emptied, a minute pore was visible in the wall between the two gametangia. By 12:20 the smaller gametangium had begun to collapse. ×787.—Fig. 45. One day later. Zygote wall thickening, now two layered. Oil globules coalescing to form larger globules. ×787.-Fig. 46. Two days later, zygote nearly mature. Wall apparently three layered, middle layer thickest. Note large oil body. ×787.—Fig. 47-50. Stages in maturation of zygote. ×787.—Fig. 51. Showing two gametangia from different threads. ×787.—Fig. 52. Nearly mature zygote showing pore in wall through which smaller gametangium emptied. X1395.-Fig. 53. Zygote several weeks old. Note eccentric oil globule as in Achlya sp. Wall consisting of three layers: (1) thin inner greenish layer; (2) thick middle layer; (3) thin outer layer, perhaps old gametangial wall. ×1500.

Table 1. Summary of characteristics of genera of Entomophthorales.

		ENT	ENTOMOPHTHORACEAE				BASIDIOBOLACEAE
Delacroixia	Conidiobolus	Entomophthora	Empusa	Massospora	Completoria	Ancylistes	Basidiobolus
Saprophytic mostly.	Saprophytic mostly. Saprophytic mostly. Parasitic, genous, 30 cultivated cultivated phyte.	Parasitic, entomogenous, 30 species, 3 cultivated as saprophyte.	Parasitic, ento-mogenous, 11 species, 1 cultured as saprophyte.	Parasitic, ento- mogenous.	Parasitic on fern prothallia.	Parasitic on desmids.	Saprophytic on frog dung but culturable on wide variety of substrata.

Azygospore formed by budding. Oil globule (?).	Azygospore formed. Oil globule (?).	Zygospore produced in one of conjugating cells. Lying free in female cell. Oil globule centric.	Zygospore produced in one of conjugating cells. Oil globule (?).

The maximum zygospore formation in liquid solutions occurred when cultures were grown in 0.25 per cent peptone plus 2 per cent malt extract for three days, upon which this fluid was replaced by 0.25 per cent peptone alone for two days, and then the cultures were washed and left in water. In such cultures sexual reproduction was exceedingly abundant, thus differing from cultures in which the nutrient fluids were not changed. Similar results have been obtained by Klebs, Kauffman, and others with Saprolegnia and Achlya.

While light favors the formation of conidia, the zygotes are most abundant in cultures kept in total

darkness.

The development of the zygote may be divided into three rather distinct stages; first, the formation and maturation of the gametangia; second, the union of the two protoplasts; and third, the ripening of the zygote. Conjugation usually occurs between gametangia in the same filament but may also occur between gametangia which arise from different filaments (fig. 37, 51). Segments between which conjugation occurs are in contact before the gametangia begin to swell; this is quite obvious where the conjugation is lateral but not so easy to demonstrate when conjugation is scalariform. The first indication that conjugation is going to occur between two segments is the swelling of the adjacent ends. The time from the first swelling until the gametangia are mature is about six hours. One of the gametangia, the female, swells until it becomes a spherical body about four times the diameter of the thread that bears it, while the male swells to about twice the diameter of its supporting thread. Sometimes the male suspensor empties directly into the female gametangium without the formation of a swollen male gametangium. After the two gametangia have reached mature size, the protoplasm in the suspensors flows into the gametangia (fig. 40). Usually, however, the male suspensor becomes empty before the female. Although the two conjugating segments are of about equal size at first, the female apparently contains a much larger amount of protoplasm. As a rule when the protoplasm has completely passed from the suspensor into the smaller gametangium, a wall is laid down separating the suspensor from the gametangium, and thus this structure resembles the antheridium of some species of Lagenidium or Pythium (fig. 41). This wall, at first plane, very shortly bulges outward, indicating increased internal pressure within the smaller gametangium (fig. 42). Vacuoles appear in the latter, and soon the protoplasm begins to empty from the smaller into the larger, this latter process occupying only five to ten minutes (fig. 43). For a few minutes after the smaller gametangium has emptied, a distinct pore is visible. Three to five minutes later the protoplasm in the female suspensor moves into the larger gametangium, after which it is separated from the suspensor by a wall (fig. 44). Usually after the smaller gametangium has emptied, its wall partially collapses (fig. 45,

46), but, since the wall is considerably thickened, it may remain visible for months attached to the avente.

After the two protoplasts have united, the zygote begins to mature. The wall becomes greatly thickened, after two to three days finally consisting of three layers, an outer thin, a middle thick, and an inner thin layer (fig. 46, 52, 53). It must be admitted, however, that though the wall was studied with a Zeiss water-immersion lens and oculars 15× and 20× and with an excellent source of illumination (Spencer lamp with prism), it was impossible to be certain about the inner thin wall layer. Both Thaxter (1888) and Riddle (1906) in their studies on the Entomophthoraceae showed zygotes with a two-layered wall.

As the zygote ripens, the small oil (?) bodies coalesce until finally one large globule is formed. In the thoroughly mature zygote this globule is eccentric, the structure strikingly resembling that of an eccentric egg in Achlya (fig. 53). The two may easily be distinguished, for in Achlya the protoplasm of the egg contains large dark granules, while the protoplasm in the zygote of Conidiobolus has a

whitish gleam.

Germination of zygote.—After the zygote has rested for about two weeks, it is capable of germination. It may retain its vitality for at least six months, perhaps longer. Zygotes dried in agar for six months were still capable of germination. The detailed stages in germination have not been followed, but it has been observed that during germination the oil globule disappears and the whitish protoplasm becomes coarsely granular. The zygote may then form a hypha which grows into a new mycelium or it may produce one conidiophore.

Contrasts with other fungi.—In view of the success of Blakeslee in securing imperfect hybridization between different species of mucors, it seemed of great interest to try such reactions between Conidiobolus Brefeldianus and other supposedly related forms. Accordingly the following contrasts have been made on agars No. 35 and 41, on both of which many zygotes are formed in C. Brefeldianus and very few conidia: C. Brefeldianus X C. villosus (Chapel Hill strain); C. Brefeldianus X C. villosus (Cornell strain from White); C. villosus (Cornell) X C. villosus (Chapel Hill); C. Brefeldianus X Basidiobolus ranarum (from Maneval); C. villosus (Cornell) × Basidiobolus ranarum (from Maneval); C. villosus (Chapel Hill) × Basidiobolus ranarum (from Maneval). In all cases the results were negative.

Comparison of Conidiobolus with other genera of the Entomophthoraceae.—The writer is following the suggestion first made by Raciborski (1896) and later followed by Claussen (1924) and Gaümann (1926) and excluding Basidiobolus from the Entomophthoraceae, placing this in a family of its own, the Basidiobolaceae. This action is fully justified by the researches of Fairchild (1897), Raciborski (1896), Olive (1907), Levisohn (1927), and others on Basidiobolus, which need not be reviewed here, and, as a further indication that this genus should be separated, the writer has found that the cell wall of Basidiobolus contains cellulose as indicated by a beautiful deep pinkish-purple reaction with chloroiodide of zinc, while species of Conidiobolus, Ancylistes, and Empusa which have been tested do not give such a reaction. From the above it is obvious that the relationship of Conidiobolus to Basidiobolus is remote.

The fungus known in this country as Conidiobolus villosus Martin must be compared with the genus as represented by C. utriculosus and C. Bre-This fungus was first described by Costantin (1897) as Boudierella coronata, renamed Delacroixia coronata by Saccardo and Sydow (1899), and has since been collected and studied by Gallaud (1905), Gilbert (1919), Martin (1925) (who named the fungus Conidiobolus villosus), White (1937), and Kevorkian (1937). The writer has also isolated and now has in culture the same species from the old sporophyte stalks of Nardia where it was growing as a weak, endophytic parasite. The fungus has been regarded as a saprophyte or perhaps a weak parasite. In his recent paper Kevorkian (1937) reports studies on the same fungus from living termites and, because of the morphological similarities between the forms studied by Costantin, Gallaud, Gilbert, Martin, and himself, has reduced all of these to synonomy. Furthermore, in view of the ability of the saprophytic Delacroixia coronata to parasitize termites and the ability of certain parasitic species of Empusa (Brefeld, 1884; Sawyer, 1929; and others) to live as saprophytes, Kevorkian places the species Delacroixia coronata (Cost.) in the genus Entomophthora. The writer agrees with Kevorkian's first conclusion but thinks it inadvisable to reduce the genus Delacroixia to synonomy with any other genus of the Entomophthoraceae until the zygospores of the former have been found. The genus Delacroixia is very close to Conidiobolus (see Gallaud, 1905; Martin, 1925); indeed, until the zygospores of Delacroixia are discovered, the villose resting spores of the latter must serve as the sole means of distinguishing the two. Likewise Delacroixia may be distinguished from Empusa (see table 1) by the villose resting spores.

Before a comparison can be made between Conidiobolus on the one hand and Entomophthora and Empusa on the other, it is necessary to discuss briefly the status of the two last-named genera. The writer feels that nothing is to be gained by combining Entomophthora and Empusa into one genus (Thaxter, 1888) but prefers to follow Nowakowski (1883) and other European students of this group in recognizing both genera (see also Sawyer, 1929). In table 1 the more important characters of the genera of the Entomophthoraceae are given. It may be seen that at present the chief differences between the two genera Empusa and Entomophthora are that in Entomophthora the co-

nidiophores are branched and the conidia are uninucleate, while in Empusa the conidiophores are unbranched and the conidia are multinucleate. Another important difference in the two genera which has apparently been overlooked by others but which shows up strikingly in Thaxter's figures has to do with the shape of the conidia. In Empusa the primary conidia are mostly globose, while in Entomophthora the primary conidia are elongate. A careful study of the structure of the conidiophore and the mode of conidial discharge is urgently needed in both genera. According to the cytological researches of Olive (1906) there are at least two methods of spore ejection in the six species of Empusa (including Entomorphthora sp.) investigated by him.

From the table and the above discussion it is obvious that Empusa with its multinucleate mycelial segments, unbranched conidiophores, spherical or broadly ovoid, multinucleate conidia, is closer to Conidiobolus than is Entomophthora with its branched conidiophores and elongate, uninucleate conidia. It will suffice, therefore, to differentiate between Empusa and Conidiobolus. As pointed out by Thaxter (1888), Empusa may be separated from Conidiobolus by the fact that in Empusa (and Entomophthora) we have a zygospore or azygospore formed by budding, while in Conidiobolus the spore is produced directly within one of the conjugating cells (see also Riddle, 1906; Nowakowski, 1877). This difference in the formation of the zygospore is of fundamental importance and should be emphasized as the main generic distinction between Conidiobolus and Empusa. Even if we are forced to abandon the physiological distinction between Conidiobolus and the entomogenous forms, this striking morphological distinction will still be of generic importance. It seems to the writer, however, that before this physiological distinction can be abandoned, much more work needs to be done, for of the forty or more species of Entomophthora and Empusa only four have yet been isolated in culture (Sawyer, 1929, p. 90 et seq.).

The remaining entomogenous genus, Massospora (Spear, 1921), with its spores borne in locules as in certain Gasteromycetes (Goldstein, 1929), is so distinct from any of the other genera that comparison is superfluous.

The two remaining genera Completoria (Lohde, 1874; Leitgeb, 1881; Atkinson, 1894) and Ancylistes (Berdan, 1937, 1938) are obligate parasites on plants, the former in fern prothallia, the latter in desmids. So far no one has been successful in culturing either of these as saprophytes. Miss Berdan, in our laboratory, tried growing Conidiobolus villosus and C. Brefeldianus on fern prothallia, but without success. From a morphological standpoint not enough is known of the conidia and the mode of formation of the resting spore (?) in Completoria to justify comparison with Conidiobolus. The genus Ancylistes, our knowledge of which has recently been greatly extended by Miss Berdan,

shows some rather striking affinities with Conidiobolus. The conidiophores, the mode of discharge of the conidia, and the appearance of the columella and stalk after discharge are strikingly alike in both genera. In sexual reproduction, however, Ancylistes is distinct from all other genera in this order in that in Ancylistes (except perhaps for A. Pfeifferi) the contents of the male cell or gametangium pass into the female gametangium through a tube which arises from the male cell (Pfitzer, 1872; Dangeard, 1906; Berdan, 1938). In Ancylistes the zygote retracts from the wall more than in either Conidiobolus utriculosus or C. Brefeldianus. Indeed, in Ancylistes Pfeifferi (Berdan, 1938) this retraction is such that the zygote in the old mother cell wall, which is composed largely of blunt protuberances, resembles the ripe oogonia of Achlya glomerata in a most striking way. It is obvious, therefore, that though Conidiobolus and Ancylistes are closely related, they should remain distinct.

Finally the question arises: Is the sexual process in Conidiobolus and Ancylistes oomycetous or zygomycetous? Brefeld (1884) considered the sexual process in Conidiobolus distinctly comycetous, and in C. utriculosus and the present species the smaller gametangium resembles an antheridium, but the larger gametangium only superficially resembles an oogonium for the simple reason that no egg is differentiated in this structure. Even in Ancylistes, where the resemblance of the sexual organs to those of the oomycetes is so marked that this has been the only reason for placing the genus with Lagenidium (Pfitzer [1872] noted the absence of cellulose as indicated by the chloroiodide of zinc reaction), the comvectous appearance is of no phylogenetic significance, for no egg is differentiated in the female structure, and the structure which resembles an egg is the zygote. Another peculiarity in zygote formation in Ancylistes and Conidiobolus is the cutting off of one or several empty cells from the female cell (Pfitzer, 1872). This usually occurs after plasmogamy but may occur while the male protoplast is flowing into the female cell. Thus, the zygote is formed not in the cell in which plasmogamy occurred but only in part of it. Moreover, the nuclear behavior during sexual reproduction of Conidiobolus agrees with that described by Olive (1906) and Riddle (1906) for Entomophthora in that both gametangia are multinucleate, but nuclear fusion, if it occurs in Conidiobolus, must take place during zygote germination.

#### SUMMARY

Conidiobolus Brefeldianus n. sp., characterized by its delicate growth, small conidia, and small zygospores, is described.

The fungus is culturable on a great variety of plant and animal substrata and is capable of para-

sitizing certain insects.

The formation of conidia is determined by proper aeration, favorable nutrients, and light. On favorable nutrient material conidia are formed in continuous darkness or continuous light. The number of conidia is greatly increased on any favorable culture media if the culture is exposed to alternating daylight and darkness.

Conidial formation is very rapid, the whole process taking from fifty minutes to two hours. When mature, the conidium hurls itself horizontally for 5 to 12 mm. by the sudden outpushing of the papilla. This force acts against the cone-shaped columella. The turgor of the conidiophore is maintained by a conspicuous vacuole, and if the latter is plasmolized, the conidium fails to get away.

Sexual reproduction occurs on a great variety of culture media but is most abundant in media relatively rich in peptone. Conjugation is usually lateral but may occur between two gametangia from different threads. The gametangia are of unequal size, the smaller always emptying into the larger to form the zygote. Both gametangia are multinucleate, as are also the zygotes. Nuclear fusion has not yet been observed. The ripe zygote has a large eccentric fat (?) globule and whitish cytoplasm surrounded by a three-layered (?) wall.

The zygote may germinate after about two weeks' rest but will retain its vitality for at least six months.

Contrasts with two strains of *Delacroixia coro*nata as well as with *Basidiobolus ranarum* produced no imperfect hybridization.

Conidiobolus is compared with the other genera of Entomophthoraceae and because of its saprophytic habit and method of zygospore formation is retained as a valid genus.

Basidibolus is shown to have cellulose walls by the chloroiodide of zinc reaction, thus verifying its position in a separate family.

# EVIDENCE FOR THE PRESENCE IN CERTAIN ETHER EXTRACTS OF SUBSTANCES PARTIALLY MASKING THE ACTIVITY OF AUXIN <sup>1</sup>

#### Richard H. Goodwin

Positive curvatures<sup>2</sup> of Avena coleoptiles upon inilateral application of various plant extracts in igar have been reported by Stark (1921), Nielsen (1924), Seubert (1925), Czaja (1934), Höfner (1937), Stewart, Bergren, and Redemann (1939), and others. The writer also has obtained positive urvatures ranging between 6° and 19° (d values 1.16 to 0.58) from ether extracts of Taraxacum oots while testing for the auxin content by the Avena technique of Boysen Jensen (1937). These indings suggest that substances other than auxin any frequently be present in extracts and that they have a toxic or inhibiting effect upon the growth f the Avena coleoptile. In testing extracts for their uxin content by the Avena method, the presence of

<sup>1</sup> Received for publication November 12, 1938.

This investigation was carried out in the Plant Physilogy Laboratory of the University of Copenhagen during the tenure of an American-Scandinavian Foundation ellowship. The writer wishes to thank Professor P. Boy-in Jensen for making available the facilities of his laboratory and to express appreciation for his helpful sugestions and keen interest in the work.

<sup>2</sup> Curvatures toward the applied agar block as conasted with the negative curvatures normally obtained ith suitable concentrations of growth-promoting subances. such substances would tend to counteract or mask the activity of the auxin, thereby introducing errors in quantitative determinations.

The purpose of this investigation is to throw further light upon the nature of ether extracts from corn meal and *Vicia Faba* shoots. Experiments were planned to ascertain whether or not masking substances were present in these extracts. The likelihood of the masking substances having the same molecular weight and hence the same diffusion coefficient as auxin would be small. Therefore, determinations of the diffusion coefficients of the auxin in the extracts were made as described below. These were compared with the theoretical values for auxin a and auxin b, natural growth-promoting substances found in higher plants.

Diffusion coefficients were determined by the method of Graham (1861) as applied to substances influencing cell elongation in Avena by Went (1928) and Heyn (1935). The method as used in the present investigation consisted in allowing the active substances present in discs of 1.5 per cent agar, 1 mm. thick, and 100 mm.<sup>3</sup> in volume, to diffuse at 20°C. into stacks of three other similar discs of pure agar. After a given time the four discs were

separated, and 12 blocks 4 mm.<sup>3</sup> were cut from each. The activity of the substances contained in the blocks was determined by the Avena test of Boysen Jensen (1937). Exact details of the test conditions in this investigation have been described by Goodwin (1939). From these data the percentage of active substances present in each of the four discs was calculated. Kawalki (1894) gives a table (modified from Stefan, 1879) of the theoretical percentages of any pure non-electrolyte in each of

four equal layers after diffusion, for various values of the expression  $h^2/4Dt$  (or x), where h is the thickness of each layer in cm., t is the time in days, and D is the diffusion coefficient of the non-electrolyte. By means of this table the corresponding values of x for the empirical percentages obtained in each diffusion experiment were determined by linear interpolation.

The accuracy of the method was first tested with 3-indole acetic acid (molecular weight (M) = 175; diffusion coefficient at 20°C.3 = 0.529). Discs of 1.5 per cent agar containing 0.24 mg. of 3-indole acetic acid per liter were diffused for one hour, under which conditions  $h^2/4$   $t = 0.1^2/4$  (1/24) =0.06, and the theoretical value of x is 0.1135. The results are given in table 1. A pronounced gradient was obtained in each case (columns 3 and 4), and the average diffusion coefficient is very close to the theoretical value. Since the coefficient of variability of the averages of the diffusion experiments is not much larger than that of direct tests as shown in table 2, the variability of the results may be attributed in good part to the test method. The errors introduced by the diffusion technique are not large.

Determinations of the diffusion coefficients of auxin in ether extracts of plant material were then made. Stock auxin extracts were prepared from corn meal by the following method, recommended by Boysen Jensen: 200 g. of coarse corn meal, freshly-ground from dormant kernels, were covered with 400 cc. of peroxide-free ether (1 liter of ether shaken with 0.5 g. CaO + 2.5 g. FeSO<sub>4</sub> + 10 cc. water and distilled) for about 48 hours and shaken occasionally. The ether extract was then drawn off, filtered, and evaporated to about 30 cc. In order to separate the auxin from excessive fats, the extract was shaken in a separating funnel with two changes of basic, saturated glucose solution (25 cc. glucose solution + 1 cc. 8 per cent NaHCO<sub>3</sub>) for five minutes each. The basic ether fraction was then discarded. The glucose solution was acidified with 3 cc. of 10 per cent tartaric acid and shaken with three successive changes of 35 cc. of fresh ether for

 $^3$  D<sub>20°C.</sub> =  $7/\sqrt{M}$  =  $7/\sqrt{175}$  = 0.529 (see öholm, 1910).

<sup>&</sup>lt;sup>a</sup> Standard deviation of the mean.

five minutes each. The glucose was then discarded. The acid-ether fraction was evaporated to about 1 cc. and the residue made up to 25 cc. of chloroform.

Measured amounts of these stock solutions were diluted from time to time and suitable quantities evaporated to dryness, taken up in 0.8 cc. of ether and slowly dropped onto pure 1.5 per cent agar discs, where the ether was evaporated according to the micro-method of Boysen Jensen (1937). Each agar disc was composed of two layers, the bottom one 1 mm. and the top one 0.25 mm. thick. The top layer along with any relatively water-insoluble scum was removed about an hour after the ether was evaporated.

The assumption was made that the auxin in the extracts had a larger molecular weight than 3-indole acetic acid. Hence, diffusions of the extracts within the stacks of four discs were carried out for 1.25 hours, a slightly longer period of time than in the previous experiments. In this case  $h^2/4t =$ 0.048 and a suitable gradient should be obtained with auxin a (M = 328) or auxin b (M = 310). The results of diffusion experiments with four different extracts are given in table 3, columns 2 to 5, and are summarized in table 4. It can be seen that in each first diffusion  $x = h^2/4Dt$  is much too low and the diffusion coefficient (D) too high for auxin a or b. When about five times as much of the same extracts was dropped originally and was diffused for 1.25 hours as usual, and the bottom discs of each stack were then diffused for another 1.25 hours, each one on three more discs of pure agar, the results of these second diffusions, shown in table 3, columns 7 to 10, and summarized in table 4, are in each case significantly closer to the theoretical values for auxin a and b. Since the diffusion coefficient of a single pure substance should, under comparable conditions, be constant, we may conclude that we are not dealing with a single substance in these extracts.

It should be pointed out that standard deviations of x and D for 3-indole acetic acid and for second diffusions of corn meal extracts are of the same magnitude (see table 4). This indicates that no further errors have been introduced.

These results may find an explanation in the following hypothesis-namely, that in addition to auxin, substances which have a molecular weight greater than auxin and which mask the effect of the auxin either by directly inhibiting cell elongation or by inactivating or otherwise reducing the growthpromoting effect of the auxin, are present in the extracts. These substances of larger molecular weight should diffuse more slowly than auxin, their relative concentration and hence their masking effect should be greatest in the first disc, and the gradient determined should be smaller than the correct value for auxin. Note in table 3, column 5, that the percentage of activity in the first disc is consistently low. Table 5 shows these low percentages to be experimentally significant. In second diffusions

a Standard deviation of the mean.

there should be much less of the masking substances present, and hence the diffusion coefficients should be nearer the theoretical value for auxin.

The following alternative explanations do not appear to be feasible. If a masking substance of lower molecular weight than auxin were present, relatively higher percentages of the substance should be obtained in the fourth disc after diffusion, resulting in a steeper gradient and hence a smaller diffusion coefficient than that expected for auxin. This effect would be accentuated in the second diffusion. If, on the other hand, there were two or more active substances differing in molecular weight, there would be a relatively higher percentage of substances with lower molecular weights and larger diffusion coefficients in the fourth than in the first disc after the first diffusion and hence, a larger empirical value for D in the second than in the first diffusion.

If masking substances are present in an extract in appreciable amounts, accurate quantitative determinations of the auxin by means of the Avena test cannot be made directly. To illustrate this point, the amount of auxin in WAE<sup>4</sup> per kilogram of corn meal in each of the four corn meal extracts was calculated by three different methods: first, from direct tests of the solution by the method of Boysen Jensen (1937); second, from an average of the values obtained in the first diffusion; and third, from an average of the values obtained in the second diffusion (assuming that 13.4 per cent of the auxin—the theoretical amount for auxin a—reaches

the bottom block by the end of the first diffusion). The results are shown in table 6. With the exception of the last extract which appears to be relatively pure, calculations from second diffusions are about twice as large as those from first diffusions. Since second diffusions were all carried out on the day following the first diffusions, loss of activity during this time may have reduced the true magnitude of the discrepancy.

The diffusion coefficients of a few more extracts are shown in table 7. Masking substances appear to be present in extracts of both endosperm and embryos of maize and also in extracts of green *Vicia Faba* shoots.

#### SUMMARY

Determinations of the diffusion coefficient of auxin in ether extracts of corn meal and Vicia Faba

shoots were made. The values obtained did not agree with the theoretical diffusion coefficients for auxin a or b. The evidence suggests that this discrepancy is due not to an auxin of different molecular weight, but rather to the presence in the extracts of substances which partially mask the biological effect of the auxin on Avena coleoptiles. At least some of these substances are ether and water soluble, with molecular weights larger than auxin. Partial purification of auxin extracts can be made by diffusion methods. When determining the activity of unknown extracts, the possible presence of such masking substances should not be overlooked. If they are present in appreciable amounts, the actual quantity of auxin in an extract may be greater than that detected by the Avena test.

## THE CAUSE OF NATURAL PARTHENOCARPY 1

Felix G. Gustafson

THAT IT is possible to produce parthenocarpic fruits artificially by treating the pistil of a flower in the bud stage with growth promoting substances or auxins, as they will be called in this paper (Went and Thimann, 1937), has now been shown by several investigators (Gustafson, 1936; Hagemann, 1937; Gardner and Marth, 1937). From this fact and the fact that auxin is known to be widely distributed in the higher plants we may assume that auxin naturally plays a part in the growth of a fruit. If so, where does it come from?

Suggestions have been made that the auxin comes from the pollen or the developing seeds (Dollfus, 1936; Gustafson, 1937, 1938a). Laibach (1932) and Thimann (1934) have shown that pollen contains auxin. As to the latter suggestion, it will suffice to point out that there are fruits without seeds such as the orange, lemon, grapefruit, banana, grape, cucumber, and others. Recently Gustafson (1938a, 1938b) proposed the hypothesis that the reason some plants produce fruits parthenocarpically is that the ovaries of these plants contain, in the flower bud stage, enough auxin to cause them to commence growing without fertilization, while the ovaries of other plants commence growing only after pollination and fertilization have augmented the auxin supply already in them. We may then think of the usual fruit growth as being initiated by pollination and fertilization, which brings into the ovary a sufficient quantity of auxin from the pollen grains and pollen tubes to start the enlargement of the ovary (Gustafson, 1937), and continued by the additional auxin produced by the developing embryos and seeds, which diffuses into the ovary

1 Received for publication December 7, 1938. Paper from the Department of Botany of the Univer-

sity of Michigan, No. 681.

The writer wishes to express his thanks and appreciation to F. W. Went, E. G. Anderson, J. Van Overbeek, and Wm. S. Stewart of the California Institute of Technology, to J. W. Lesley, H. B. Frost, and I. J. Condit of the Citrus Experiment Station, Riverside, California, to C. S. Pomeroy of the U. S. Department of Agriculture, Riverside, and to W. E. Lammerts, Ontario, California, for various aids extended during the course of this investigation and to the Directors of the Horace H. Rackham Trust Fund of the University of Michigan for financial aid.

to supply what is needed. Contrasted with this is the formation of a fruit from an ovary which contains enough initial auxin within itself to start enlargement without any additional being derived from pollination and fertilization, the resulting young fruit either producing its own auxin or obtaining it from the leaves. The fruits produced in this way are parthenocarpic.

The purpose of this investigation was to compare the auxin concentration in the ovaries, at flower bud stage, from plants that produce fruits parthenocarpically and from plants that require fertilization.

PROCEDURE.—The work here reported was done at the William G. Kerckhoff Laboratories at the California Institute of Technology. The citrus material was obtained either from the Citrus Experiment Station at Riverside or from the Armstrong Nurseries at Ontario, California. All the grape material came from the Armstrong Nurseries. The growth hormone content was determined by the Avena method, the technique of which has been discussed in detail by Went and Thimann (1937).

The auxin was extracted with freshly distilled ether according to Van Overbeek's (1938) modification of other methods. The dried residue was thoroughly mixed with a small amount (usually 0.4 to 0.8 cc.) of 1.5 per cent agar, and after standing 90 minutes was poured into a nickel plated brass mold  $1.5 \times 8.0 \times 10.5$  mm. in size. After the agar had been cut level with the surface of the mold, the large block was cut into 12 equal pieces. The material was now ready for the test. Great care was taken to have freshly prepared extracts. Usually the extract was prepared the same day that it was used, but if it could not be used the same day that it was made, it was always stored in a refrigerator in dried condition. The extraction was always carried out in the dark and usually, though not always, at a low temperature.

Control experiments in which Avena plants were treated with a known concentration of indole acetic acid (usually 21.5 gammas per liter) were run with every experiment. By this means the sensitivity of the test plants was determined for each experiment, which was very important because there was considerable variation day by day, and the auxin

Table 1. Auxin content in the ovaries of unopened flowers and in young fruits of oranges and lemons.—The auxin concentration is denoted in terms of indole acetic acid equivalents, and the figures are gammas per kilogram of fresh material.

concentration in a plant can be calculated in terms of indole acetic acid (see Van Overbeek) rather than in terms of some of the many units which have been employed by different investigators.

A few experiments were performed in which the plant material was placed on the agar blocks as in Went's original experiments. In most instances such blocks when placed on Avena coleoptiles caused no curvatures. It had been hoped that this method could be used, but since so few plants gave any results it was abandoned for the extraction method.

RESULTS AND DISCUSSION.—It very soon became obvious that one could not profitably compare unrelated species with one another because the difference in the auxin content in the vegetative parts of different species varies greatly. Therefore it was necessary to obtain varieties of the same species that were parthenocarpic and non-parthenocarpic. Fortunately, the nearby Citrus Experiment Station at Riverside had a great variety of oranges, some producing seeds and others not. Through the courtesy of Dr. H. B. Frost an abundance of flower buds and young fruits were obtained from several varieties that were selected after a careful investigation of relationships. Two

varieties of oranges were also obtained from the Armstrong Nurseries at Ontario through the courtesy of Dr. W. E. Lammert, and the Seedless Valencia Rico No. 1 was obtained from Mr. C. S. Pomeroy of the U. S. Department of Agriculture at Riverside.

The varieties finally used were the seedless Navel varieties Washington and Robertson, the latter being a sport of the former; Paper rind, a seeded form; three varieties of Valencia—the ordinary seeded variety, a seedless sport of the seeded variety called Armstrong, and a seedless form called Rico No. 1, which was introduced from Porto Rico and may not be related to the Valencia, though it looks like it. These six varieties are very closely related to one another. Since all belong to Citrus sinensis, they can properly be compared. Satsuma, a seedless variety of C. nobilis, was also used, but it cannot be compared directly with the others. After it was discovered that there existed a tree of seedless lemons (Citrus Limonia) in Riverside, Eureka lemon was also used.

It must be stated that authorities on the subject are not agreed as to whether pollination is or is not necessary for the fruit production in oranges. Evidence points towards the lack of necessity for

Table 2. The amount of fresh material used of each variety, the quantity of 1.5 per cent agar with which the dry residue was mixed, the mean curvature of 24 Avena coleoptiles treated with this agar, the mean curvature of 24 control Avena coleoptiles treated with indole acetic acid (21.5 gammas per kg.), and the concentration of auxin in terms of indole acetic acid equivalents in gammas per kilogram fresh material as calculated by the formula  $c \times s \times v/w$ , (Van Overbeek, 1938), where c is the curvature of the experimental plants, s the sensitivity of the Avena plants or the number of gammas of indole acetic acid required to produce one degree of curvature, v the volume of agar with which the residue was mixed, and w the fresh weight of the material used.

pollination, but it is not conclusive. For this reason care was taken to use only unopened flower buds, so that there could be no possible question about the influence of pollination upon auxin content of the ovaries.

Usually about 200 large buds which were nearly ready to open were collected from each variety during the middle of the day. Within a few hours the ovaries had been removed from the buds, weighed, and placed in freshly distilled ether. The extraction time was usually two days, during which time the material was kept in an electric refrigerator. Table 1 is a composite of three such experiments.

Table 1 is a composite of several experiments, and it would be very difficult to include in it certain information which the reader might wish to know. Therefore the first experiment with lemons and oranges is given in detail in table 2. It will be noticed that not all of the oranges were used in this experiment, but nevertheless has been chosen because it is the first one and is typical of the others.

In this experiment the differences between the seeded and the seedless varieties were not nearly so large as they were in the second experiment where the figures were as follows: seedless lemon 0.70, seeded lemon 0.12, Washington navel 1.05, Valencia 0.51, Rico No. 1 (seedless) 1.16, Paper rind (seeded) 0.45, and Satsuma (seedless) 4.01 gammas per kilogram fresh material.

Table 1 shows that in every instance the auxin content of the ovaries of the buds is higher in the parthenocarpic variety than in the corresponding seeded variety. On the other hand, after the ovaries have started to grow and the fruits are two or four weeks old, the auxin concentration has increased in the seeded varieties, while in the seedless varieties, where measured, it has decreased. Besides bringing out the fact that the auxin content is higher in the ovaries of the parthenocarpic varieties than in the non-parthenocarpic, the table also shows that fertilization and seed development increase the auxin concentration of the ovary. This increase is in agreement with the suggestion previously made that the seeds supply the auxin needed in the growth of the ovary into a fruit.

It should further be noticed that the Robertson Navel has a much higher auxin concentration than the Washington. This may be associated with the greater early growth rate of the former. When four weeks old the Robertson fruits are several times as large as the Washington, and they also mature considerably earlier. Both the seedless varieties of the Valencia have a much higher auxin content than the common seeded variety, and the Armstrong, which is known definitely to be a bud sport of the seeded Valencia, has an auxin concentration four times as large as that of its parent type. The Satsuma has a surprisingly large auxin content, but unfortunately there is nothing to compare it with except in a general way.

Diffusion experiments were also tried, but only the lemon gave any results. One millimeter thick 2 per cent agar sections were cut into blocks 8.0 X 10.5 mm., and these were subdivided into 12 equal pieces which were separated from one another on a moist slide. On top of each small block was placed an ovary, and the slide was then left in a damp Petri dish for two hours. The ovaries were removed from the agar blocks, which were placed on Avena coleoptiles in the usual way. It was found that the average curvature of 24 Avena coleoptiles treated with agar blocks upon which had rested the ovaries from the seedless varieties was  $6.3 \pm 0.7^{\circ}$ , while the average curvature of 24 other Avena coleoptiles treated with agar blocks upon which had rested ovaries from the seeded variety was only  $3.3 \pm 0.6^{\circ}$ . The actual concentration was not obtained in this experiment, but Went has found that the curvature of the Avena coleoptile is proportional to the auxin concentration in the agar block with which it was treated. Therefore there is a much greater auxin concentration in the ovaries of the seedless variety than in those of the seeded variety. This is in agreement with the data from the extraction experiment with lemons.

Three varieties of grapes, Thompson and Black Manukka seedless and seeded Muskat, were obtained from the Armstrong Nurseries. The exact relationship between these three varieties is not known, but it is thought by authorities to be fairly close.

Material was collected in the flower bud stage, and the whole flower buds were used in extraction. The procedure of extraction and testing was the same as that for the oranges. Table 3 gives the results for the one test that was made with flower buds.

Table 3. Auxin content in flower buds of three varieties of grapes. Auxin concentration is denoted in terms of indole acetic acid equivalents and the figures indicate gammas per kilogram of fresh material.

	Seedless	Seeded
Thompson	Black Manukka	Muskat
2.74	1.30	0.34

The auxin content is much higher in the seedless varieties than in the seeded variety.

The three experiments with oranges extending over the whole blooming period, three experiments with lemons, one of which was a diffusion experiment, and one experiment with grapes all bring out the same fact—namely, that the ovaries of the varieties that are parthenocarpic have a much higher auxin concentration in the flower bud stage than those that develop into seeded fruits.

Conclusion.—While it is true that only three species of plants that are naturally parthenocarpic

have been investigated, yet the auxin content in the ovaries of all the parthenocarpic varieties is so much greater than in the non-parthenocarpic that there seems to be no question about this being a general condition. We can, therefore, at least tentatively or until contrary information is obtained in other species, accept the hypothesis that the reason some fruits develop without seeds is that they have a high auxin content in the ovaries at the time of blossoming and that this is high enough to set off the growth processes with the result that the ovary commences to grow even though there has been no fertilization. After growth has once commenced, it is continued either because auxin is produced in

the ovary itself or because auxin is transported into it from the leaves.

#### SUMMARY

It has been shown that the auxin content in the ovaries of flower buds from varieties of oranges, lemons, and grapes that produce fruits parthenocarpically is higher than in the ovaries from corresponding varieties that do not produce fruits parthenocarpically.

# A NEW TYPE OF EMBRYOGENY IN THE CONIFERS 1

# Phyllis L. Cook

HAVING RECENTLY completed a study of the early embryogeny of Juniperus communis, I believe that the results are worthy of publication in that they show a type of embryogeny hitherto unknown in the Conifers. Ottley (1909) studied the life history of J. communis through the first division of the zygote, and Noren (1907) and Nichols (1910) studied it through the development of the proembryo. Strasburger (1872) figured one embryo from J. communis as it appears during the first year and a single embryo from a mature seed from the same species. He also figured the proembryo and the developing multicellular embryo of J. virginiana. The process of development from the proembryo stage to the beginning of the multicellular stage is often long and complicated, and with the one exception of Strasburger's figure, no description of the process in any species of Juniperus has existed in the literature until the present. It is between the proembryo and the multicellular stages that the unique features occur.

During the last two summers, I have collected J. communis in the Muskoka Region of Ontario, where it is native, and on the campus of the University of Illinois, where it is cultivated. I have

<sup>1</sup> Received for publication December 27, 1938. To Dr. J. T. Buchholz I am indebted for direction and criticism of this study. had the privilege of studying mounted embryos of *J. communis* collected at Cold Spring Harbor, Long Island, by Dr. J. T. Buchholz, and of *J. mexicana* from Austin, Texas, also collected by Dr. Buchholz. For the study of fertilization, the proembryo, and the late embryo stages, I have used microtome sections, and for the rest of the embryogeny I have employed the Buchholz (1938) method of mounting whole conifer embryo complexes.

INVESTIGATIONS.—In Illinois fertilization takes place during the first or the second week in June, and in Ontario during the last week in June. One, two, three, or occasionally more eggs in each archegonial complex are fertilized. Nichols (1910) states that normally eight free nuclei are present before the proembryo becomes cellular, and my findings agree with his. The complete proembryo consists of about twelve cells arranged in three more or less definite tiers. The nuclei of the upper tier are never completely walled in, and they take no part in further development; the cells of the middle tier elongate, pushing the cells of the lowest tier out of the archegonium into the nutritive tissue of the gametophyte. In the cavity which they form in the gametophyte, the cells which constituted the two lower tiers of the proembryo begin a process of development which is unique in the Coniferales and

approximated elsewhere only in the Gnetales (Land, 1907; Thompson, 1916; Haining, 1920; fig. 13). It immediately becomes apparent that each cell of the elongated tier as well as each cell of the lowest tier is a potential embryo initial, for both tiers elon-

gate similarly. In this elongation the cells of the middle tier sometimes push aside those of the lowest tier because of a difference in their rates of elongation (fig. 4). It is more usual, however, for the lowest tier to maintain its position in spite of the more rapid elongation of the tier above, and consequently its cells are pushed ahead (fig. 3). It should be remembered that the products of each zygote are undergoing the same process; so that the number of embryonic units present in an ovule at this stage is theoretically eight times the number of the original zygotes in the complex. All the cells continue to elongate, but because of their more favorable position at the start, the cells of the lowest tier are likely

to reach farthest into the nutritive tissue of the gametophyte. A number of them are usually tied for first place; so that at the very beginning of sporophytic life, there is keen competition among individuals (fig. 3). Occasionally when individual units elongate at varying rates, the resulting complex may be more U- or V-shaped (fig. 2) than truncate in outline (fig. 3); and then the units farthest advanced may immediately give rise to multicellular embryos. The truncate type of complex, however, is more common; and when this is the condition, the lowest cells instead of dividing and giving rise to multicellular embryos, elongate and often lobe (fig. 4a, b, c, d, e). Two or even three lobes are frequent, each projecting in a different The single large nucleus of a tube may migrate into one of the lobes, or it may divide by mitosis and provide two or more lobes with nuclei (fig. 6). Lobes and unlobed ends of tubes then intertwine, forming a compact knot. This knot of tubes bores its way into the gametophyte tissue by means of two processes—the chemical process of digestion and the mechanical process of elongation. The rate of elongation exceeds that of digestion, so that the ends of the tubes are thrust into undigested. compact tissue. This condition makes it difficult to dissect out the complex of tangled tubes cleanly, and after dissection the finger-like ends of the tubes usually still hold fast to masses of nutritive cells. Sometimes nucleated lobes segment from the rest of the tube (fig. 6), but often they remain open. After the tubes grow to a certain length (15 to 20 microns), the nucleus divides, and a wall between the two daughter nuclei forms a rounded cell on the end of the tube, which may now perhaps be called a suspensor. If there is not too keen competition at this point, the rounded cells may give rise to multicellular embryos, but they in turn more frequently elongate into a second set of suspensor-like tubes without end-cells. If the rate of their elongation is unequal, they will cut off cells at their tips, the farthest advanced of which will divide and form a mass of cells; but, if as is again usual, there is still a tie among a number of tubes, they again lobe and intertwine before cutting off new cells (fig. 6). Some tubes are left behind during each of these advances because of their slow growth (fig. 5, 7), but since the tubes that compete successfully during the early laps of the race are likely to lobe, the number of tubes in competition may not be appreciably diminished for some time. The lobing process is apparently more or less confined to the early sets of tubes, but the elongating-intertwining process may be repeated an indefinite number of times, forming a fairly recognizable tier of tubes for every occurrence (fig. 7).

As each new set of suspensor-tubes develops, those preceding it begin to collapse; so that the entire elongated complex resembles a much twisted and tangled rope of spaghetti (fig. 7). The elongated cells that constituted the middle tier in the proembryo and the next to the last formed tier of tubes remain fairly turgid, while the very last tubes are extremely round and plump (fig. 7, 8). The nuclei present in the tubes after the end-cells are cut off are large at first, but they soon disintegrate (fig. 7).

Eventually because of varying rates of elongation and the loss of numerous tubes, the competition among potential embryos does become less keen than at first, and the tubes that have penetrated the farthest cut off end-cells that give rise to multicellular embryos (fig. 8). Mitoses take place, and the apical cell method of growth is established (fig. 8). The single suspensor-tubes swell to an enormous size at this stage (fig. 9). The gametophyte tissue is continuously being digested away; but the embryos proper are nearly always located a little ahead of where the digestion has been the most complete, which would suggest that it is the tubular suspensor cells that secrete the digestive enzymes perhaps more than the cells of the embryo itself; or the condition may only be due to the fact that digestion is slower than elongation. When the embryo consists of about a dozen cells, those cells on the outside and farthest from the growingpoint elongate backwards, forming a massive secondary suspensor and also pushing back any embryos that may still be competing (fig. 10). Since the number of tiers of suspensor tubes is indefinite, the time of multicellular embryo formation also varies; so that in a batch of ovules collected from the same plant six months after fertilization, it is possible to find embryo complexes with embryos in all but the last stages of differentiation. Thus there is no definite wintering-over condition as Strasburger (1872) supposed there was.

Although several embryos in an ovule may become multicellular, more than one that is completely differentiated is rare in a mature seed. Aborted embryos are often found entangled with the collapsing suspensor of the successful one (fig. 11). The mature embryo normally has two cotyledons, and in the two growing seasons required for its full development, it replaces most of the gametophyte tissue with its own bulk.

Discussion.—This investigation of Juniperus communis has disclosed a type of embryogeny different from that found in any of the other genera of the Coniferales. In no other genus of the order do we find the lowest cells of a proembryo elongating without first cutting off embryonic cells at their tips. As long ago as 1872, Strasburger described the tangled skein of tubes in the ovule of Juniperus communis and remarked that in dissecting the complex, it was easy to lose the end-cells. He probably saw the elongating suspensor-tubes in many of his dissections, and thought that he had lost off the terminal cells. This is perhaps true in complexes dissected some weeks after fertilization; but in the early stages I believe that nothing is lost, because

when there is close competition among embryonic units, they elongate before cutting off end-cells, so that there are no small cells present to be lost.

In the organization of the first products of the zygote and in their subsequent behavior, J. communis is similar to Ephedra trifurca as described by Land (1907) and to Gnetum as described by Thompson (1916) and by Haining (1920). In

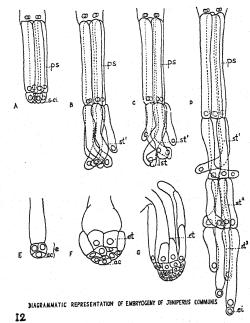

Fig. 12. Juniperus communis. Diagrammatic representation of the embryogeny of the product of one zygote. A, proembryo of three tiers. B, prosuspensor cells and terminal cells elongated. C, terminal cells, elongating, lobing, intertwining, two tubes being left behind. E. trifurca the fusion nucleus gives rise to eight free nuclei. Three to five of these with their surrounding cytoplasm become separated from the rest of the cytoplasm by walls, and each one is a potential embryo initial. The nucleus divides, forming two nuclei which become unequal in size. A large vacuole forms in the upper part of the cell, and two lobes are put out by the cell wall at points nearest the nuclei. The lobe near the larger nucleus elongates, and the other disappears. After the tube has elongated, the larger nucleus moves down into it almost to its tip, and a cleavage ring forms behind and separates the cytoplasm into two masses. The smaller nucleus then migrates down the suspensor-tube (fig. 13, A, B, C, D, E).

In Gnetum sp. 33 (Thompson, 1916), the fusion nucleus gives rise to a group of cells, each of which is a potential embryo initial. Each initial elongates apparently without the division of the nucleus and penetrates deeply into the gametophyte. Although Thompson has sometimes seen two or more nuclei in a tube, he believes that "a single enormously large nucleus" is usually the only one present. In this species he never saw walls and very little branching of the tubes. In G. gnemon only two cells are formed by the division of the fusion nucleus, and each one is an embryo initial.

In G. funiculare Haining (1920) did not see early post-fertilization stages, but her figures F, G, and H

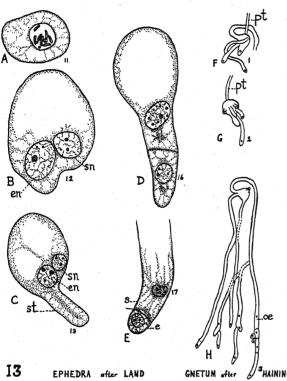

Fig. 13. Land's (1907) figures 11, 12, 13, 16, 17 of Ephedra trifurca, showing the early development of one embryo initial. Note the elongation of the tube and the migration of the nucleus. ×250.—Haining's (1920) figures 1, 2, 3 showing the branching and elongation of tubes in one embryo initial in Gnetum funiculare. Note the absence of small terminal cells. ×25.

of my figure 13 show "a large, single-celled proembryo" from which several "suspensors" have grown. The nucleus has divided, and one daughter nucleus has migrated to the tip of each tube. Each tube branches, and cross-walls separate the branches from the main tube and also any two nuclei in one tube.

In Juniperus communis the fusion nucleus gives rise to about twelve nuclei, eight of which become completely walled in. All eight are potential embryo initials. The four of the upper tier assume the function of suspensors and push those of the

lower tier out of the complex. The nuclei of the embryo initials that become suspensors do not divide, but the cells elongate and sometimes lobe. It is common for the embryo initials of the lower tier to elongate and lobe, and the nucleus of each may migrate into one tube, or it may divide and supply two or more tubes.

In the comparison of these four species, it becomes apparent that there is confusion in the use of the term "proembryo." In describing the embryogeny of the Coniferales, Chamberlain (1935) uses the term "proembryo" as a collective name for the products of a single zygote before they break through the base of the egg. In describing Ephedra, Land (1907) uses the same term to designate each of the eight cells formed by the division of the zygote, and Thompson (1916) describing Gnetum, uses the term to cover the whole group of cells formed by the division of the zygote. It is clear from this study that the constituent cells of the "proembryo" of Chamberlain and Thompson are the homologues of the "proembryos" of Land and that the eight walled cells of Juniperus are the homologues of the three to five cells of Ephedra, of the indefinite number of walled cells in Gnetum sp. 33, and of the two cells in G. gnemon. If we speak of all these homologous units as embryo initials, we may avoid some confusion. The subsequent elongation of the individual embryo initials is similar in Ephedra trifurca, Gnetum sp. 33, G. gnemon, and in Juniperus communis, except that in Ephedra the nucleus divides prior to the elongation of the cell. Although Juniperus is unique in the Coniferales in the behavior of the lowest embryo initials, many features of its embryogeny are found elsewhere in the Cupressaceae. The products of the fusion nucleus before they break out of the egg are arranged similarly in Juniperus, Thuja, Biota, Cupressus, Libocedrus, and Chamaecyparis. Like all these genera except Thuja, Juniperus exhibits cleavage polyembryony, but the cleavage takes place very early. Often the cells of the middle tier separate as they do in Chamaecyparis (Buchholz, 1932), so that embryos sometimes form on the ends of cells of both tiers.

The affinities of the Gnetales have always been in question. Land could see no proof for their relationship to any living group, but he recognized that they had many characteristics of the Coniferales, and he thought they had more in common with the Taxaceae than with any other family. He did not state specifically what characteristics he was considering. Arber and Parkin (1908) believed that the Gnetales had been derived from Cycadalean stock on a basis of their floral organization. Thompson's (1912) studies have led him to favor Coniferous relationship, although he has not seen proof for a Gnetalean descent from any modern group of Conifers. Among the points of similarity between the two groups, he mentions the arrangement and structure of the tracheid pits, bars of Sanio, tertiary spirals, trabeculae, primitive uniseriate and lignified rays, lack of centripetal and presence of centrifugal wood in the leaf-trace, and the structure of the vascular bundles of the leaves. Buchholz (1920) called attention to the occurrence of cleavage polyembryony in the Gnetales and suggested that this feature connects the Gnetales with the conifers rather than with the cycads. Again Buchholz (1929) referred to the similarity between Coniferous and Gnetalean embryogeny and remarked that "the character of the proembryo (of Ephedra) fits in very beautifully as a derivative of some form having an early embryogeny resembling that of Biota." His hypothetical form might well be Juniperus, for the present study of J. communis makes possible an easy transition from the typical Cupressacean embryogeny to that of the Gnetales; so that the organization of the products of the fusion nucleus and the elongation and branching of the embryo initials may now be added to Thompson's list of similarities between the Coniferales and the Gnetales. In the 1929 paper, Buchholz also mentioned the opposite or whorled arrangement of the leaves in the Cupressineae and the Gnetales. I have found no mention in the literature of two other similarities between the groups—namely, (1) the fact that the cells lining the micropylar cavity are large and elongated at right angles to the axis in Gnetum and in Juniperus and (2) that pollen grains germinate in the micropylar cavity in Gnetum and sometimes, at least, in Juniperus. It seems, therefore, that the Gnetales are related to the Coniferales and that the relationship exists between

them and one of the living Coniferous families, the Cupressaceae.

#### SUMMARY

The early embryogeny of Juniperus communis is described, disclosing a type of embryogeny unique in the Coniferales and approximated elsewhere only in the Gnetales.

The products of division of the fusion nucleus organize in three tiers of four nuclei each, the lower eight of which are completely walled in. The eight walled cells are embryo initials which elongate without first cutting off end-cells. The elongated cells lobe, intertwine, and then cut off end-cells. elongating-intertwining process may be repeated an indefinite number of times, depending upon the keenness of competition among individual embryonic tubes. When competition almost ceases, the tubes farthest advanced cut off end-cells that give rise to multicellular embryos, which show apical cells.

In a batch of ovules collected from the same plant six months after fertilization, it is possible to find embryos in all but the last stages of differentiation.

The embryogeny of Juniperus communis is similar to that of Ephedra and Gnetum in (a) the organization of the products of the division of the fusion nucleus, (b) the early establishment of cleavage polyembryony, and (c) the elongation and branching of the embryo initials. The similarity of embryogeny may be taken as additional evidence in favor of a relationship between the Coniferales and the Gnetales through the Cupressaceae.

# EXPERIMENTAL METHODS FOR THE STUDY OF THE ROLE OF COPPER, MANGANESE, AND ZINC IN THE NUTRITION OF HIGHER PLANTS <sup>1</sup>

P. R. Stout and D. I. Arnon

In investigating the rôle of zinc, manganese, and copper in plant nutrition, the use of suitable experimental methods for growing plants assumes particular importance. The amounts of these so-called microelements required by plants are so small that they are frequently supplied in considerable part or in toto by the incidental impurities included in the culture medium. A successful demonstration of the indispensability, as well as any study of the quantitative aspects of the importance of microelements in the nutrition of higher plants, depends directly on the removal of contaminants from the culture medium.

The purpose of this investigation was to develop an experimental technique which, with the use of ordinary laboratory and greenhouse facilities, would permit the undertaking, on a fairly large scale, of experiments to study the physiological importance of zinc, manganese, and copper in the nutrition of higher plants. The object was attained by using the water culture method and, by proper selection of materials and purification procedures, reducing the contaminations derived from water, chemicals, and containers. The use of very sensitive chemical tests to determine the amounts of contaminants present in the culture medium after purification made it possible to prepare nutrient solutions of equal degrees of purity. It was possible, using this technique, to obtain consistent and reproducible responses in plants from adding minute amounts of metals to the nutrient medium (for example, 1 part of zinc in 200,000,000 parts of culture solution, which amounted to  $1\gamma$  [0.001 mg.] of zinc to a plant).

GENERAL CONSIDERATIONS.—The metal contaminants found in nutrient solutions are derived from three sources: containers, water, and chemicals. Previous investigators (Steinberg, 1919, 1935; Hopkins, 1933), studying the effect of microelements on lower plants, have described successful methods for nutrient solution purification in which metal impurities were removed by precipitation and adsorption at high temperatures and slightly alkaline reactions in the presence of calcium and phosphate ions. They have applied these purification procedures to either the complete nutrient solution (Steinberg, 1919, 1935) or to one divided into two portions (Hopkins, 1933), removing in one or two operations such impurities as were derived from the several nutrient compounds, water, and con-

<sup>1</sup> Received for publication January 9, 1939.

In this investigation in which large scale experiments with higher plants were undertaken, the purification of the complete nutrient solution was found to be impracticable because of the relatively large volumes required (usually several hundred liters of nutrient solution in one experiment). Furthermore, as a result of transpiration, water, in large amounts, had to be added to the cultures before the nutrient salts needed replenishing. This was a significant consideration, since, as will be shown later, ordinary distilled water was found to be a source of metal contamination.

It was attempted, therefore, to remove metal contaminants in the nutrient medium at their source by selecting suitable containers and purifying water and each nutrient salt separately. Individual purification procedures, based on Steinberg's technique (Steinberg, 1919, 1935), were adapted for each molar stock solution of nutrient salts. In addition, large quantities of distilled water were purified by redistillation, using a Pyrex glass condenser, and Pyrex glass containers were adopted for growing plants.

After purification the purity of water and the various molar stock solutions of nutrient salts was determined by means of an adaptation of the diphenylthiocarbazone (dithizone) test. Dithizone forms colored complexes at alkaline reactions with a number of metals (Snell and Snell, 1936) and provides a very sensitive test for zinc, copper, nickel, cobalt, lead, mercury, cadmium, thallium, and bismuth. This test, as described later, permitted the detection of 0.0005 mg. and, with special care, 0.0001 mg. (0.1 of a gamma) of the combined metals listed above.

The purification procedure reduced the metal content of the nutrient salts from 500-5,000 to consistently less than 10 parts per billion, and the redistillation reduced the metal content of distilled water from 10-100 to consistently less than 1 part per billion. Each lot of water and stock solution of chemicals was tested and, if found pure, approved for future use in the preparation or the replenishing of nutrient solutions. The purified chemicals and water could thus be added independently of each other, to give nutrient solutions of equal and reproducible purity.

This investigation was directly concerned with three elements: zinc, copper, and manganese. The dithizone test, as used here, while measuring the combined amounts of zinc and copper along with the other metals listed above does not include manganese. It was found, however, by the persulfate test for the determination of manganese, that this metal was also removed in the purification process

<sup>&</sup>lt;sup>2</sup> Steinberg (1919, 1935) and Hopkins (1933) used Pyrex glassware as containers, which, as will be shown later, do not serve as a source of contamination.

along with copper and zinc. The dithizone test was adopted, therefore, as a general test for determining the removal of the aggregate metal impurities, including manganese, from each lot of purified chemicals and redistilled water.

Selection of containers for growing plants.—In preliminary experiments, various containers of black iron, porcelain, and stoneware were tested for freedom from metal contamination. These containers were coated with asphalt paint, which was found to be free from metal impurities, and were allowed to stand filled with pure water for a five-week period. From 20 to 200 gammas of metallic impurities (dithizone test) were brought into solution in this period of time, more than enough to supply the needs of plants in some cases.

No paint was effective in preventing metal containers from yielding impurities to the solution. Most paints, the asphalt (black asphaltum) paint being an exception, are themselves a ready source

of contamination.

It was known from previous experience that Pyrex glassware, as distinguished from Fry, Jena, or soft glass was satisfactory for storing various metal-free reagents. Pyrex containers have previously been used with good results in other investigations on microelements (Sommer and Lipman, 1926; Chapman et al., 1937), and, since they were not a source of metal contaminants, they were adopted in all further work. Two and four liter beakers were used. The covers, cast from plaster of Paris and soaked in hot paraffin, contained several holes in which the plants were supported with The beakers were covered with thick paper to exclude light. Recently shallow rectangular Pyrex ovenware dishes of approximately two liter capacity, with glass covers, were adopted for some experiments. The plants were supported with cotton in holes drilled in the glass covers. Both the glass dish and the cover were painted on the outside with black asphalt followed by aluminum

PREPARATION OF WATER FREE FROM METAL IM-PURITIES.—Repeated tests have shown that ordinary distilled water, from various sources, contained metal contaminants varying from 0.1 to 0.01 part per million. These impurities were traced to the generally used tin-lined copper stills and metal piping through which the distilled water circulated and also in some cases to an unsatisfactory design and too rapid rate of operation of the still, resulting in carrying over unvaporized water particles.

No consistency was found in the amounts of impurities present in different samples of water derived from a given source. Not only did water secured from different stills, or from different taps on a line from one still, contain variable amounts of metal contaminants, but also different samples drawn from the same tap in the course of a day varied in their metal content from 100 to less than 1 part per billion.

Redistilled water free from metal impurities was obtained by using a Pyrex glass trap and a Pyrex condenser and operating the still at a rate of distillation sufficiently slow to give a cool distillate.

The pure redistilled water was stored in Pyrex carboys. Each lot was tested by the dithizone test as described below.

Purification of nutrient salts.—There was no consistent relation between the market grade of salts and their freedom from metal impurities. C. P. salts from various sources contained variable amounts of metal impurities, which in certain cases exceeded those present in salts of technical or even fertilizer grade. For example, a reagent grade of potassium nitrate was found to contain 100 ppm. of metal impurities, whereas a fertilizer grade of the same salt contained 0.1 ppm. With another batch of salts entirely different amounts of impurities were found. Since all the salts were purified before use, the cheapest grade was selected in each case, provided it was free from otherwise objectionable impurities (phosphate fertilizers, for example, frequently contain appreciable amounts of fluorides).

Table 1. Nutrient salts used for purification.

Salt	Grade	Remarks
Calcium nitrate Ca(NO <sub>3</sub> ) <sub>2</sub> ·2H <sub>2</sub> O <sup>a</sup>	Fertilizer	Singularly free from metal impurities
Potassium nitrate KNO <sub>3</sub>	U. S. P.	Singularly free from metal impurities
Magnesium sulphate MgSO <sub>4</sub> ·7H <sub>2</sub> O	U. S. P.	99.9% pure
Di-Ammonium phosphate (NH <sub>4</sub> ) <sub>2</sub> HPO <sub>4</sub>	C. P.	Technical grades free from fluorides are also satisfactory
Di-Potassium phosphate $K_2HPO_4$	C. P.	Technical grades free from fluorides are also satisfactory
Ammonium sulphate (NH <sub>4</sub> ) <sub>2</sub> SO <sub>4</sub>	C. P.	

a Found by analysis to contain this proportion of water.

The kind and grade of salts used in this investigation are given in table 1. Molar stock solutions of the salts were prepared for making the nutrient solution employed in this laboratory (Hoagland and Snyder, 1933; Arnon, 1938) as well as for certain special nutrient solutions involving ammonium sulphate. As the monobasic potassium and ammonium phosphate included in these nutrient solutions cannot be treated with calcium carbonate in the purification process, the di-basic forms— $K_2HPO_4$  and  $(NH_4)_2HPO_4$ —were used. The latter were acidified after purifications with pure C. P.  $H_2SO_4$  or  $HNO_3$  (see directions below) before being added to the nutrient solution.

A supplementary iron solution containing 0.5 per cent FeSO<sub>4</sub> and 0.5 per cent tartaric acid was

added twice weekly at the rate of 0.5 cc. per liter of nutrient solution. The nutrient solutions were supplemented with the A4 and B7 solutions of microelements (Arnon, 1938), for the preparation of which tested redistilled water and C. P.  $\rm H_2SO_4$ , respectively, were used. Since only small amounts of chemicals are used in the preparation of these supplementary solutions, no purification was attempted in this case.

DIRECTIONS FOR PURIFICATION OF MOLAR SOLU-TIONS OF SALTS.—As already pointed out, molar stock solutions of each salt were purified separately, and the complete culture solutions were prepared by adding the requisite amounts of each nutrient salt to redistilled water. All the empirical purification procedures given below, although differing for the various salts, involve the use of calcium carbonate and heating the solution in the presence of calcium and phosphate ions at slightly alkaline reactions. The general considerations underlying the calcium carbonate purification method have been discussed by Steinberg (1935), who used it to purify dilute complete nutrient solutions. In the present work the calcium carbonate adsorption method has been modified to permit the purification of relatively concentrated solutions (molar stock solutions of individual salts).

Reagents needed: (1) CaCO<sub>3</sub> U. S. P. grade, precipitated, finely divided. (2) M/1 Ca(NO<sub>3</sub>)<sub>2</sub>. (3) M/1 K<sub>2</sub>HPO<sub>4</sub>. (4) M/1 H<sub>2</sub>SO<sub>4</sub> or M/1 HNO<sub>3</sub>, diluted from concentrated "C. P. acids, special for lead and arsenic determinations." Used for acidifying the purified molar solutions of (NH<sub>4</sub>)<sub>2</sub>HPO<sub>4</sub> and K<sub>2</sub>HPO<sub>4</sub>.

Molar solutions of the salts were prepared with ordinary distilled water. They were purified in five liter batches, in six-liter Pyrex boiling flasks, stoppered with a cotton plug. The purified solutions were stored in Pyrex flasks. The flasks were cleaned, prior to use, with 1-1 commercial hydrochloric acid and rinsed with distilled water.

PREPARATION OF PURIFIED SALTS.—A. Calcium nitrate or potassium nitrate.—Add 65 grams of CaCO<sub>3</sub> and 50 cc. of M/1 K<sub>2</sub>HPO<sub>4</sub> to 5 liters of a molar solution of the salt. Autoclave for one hour at 20 pounds pressure. Allow the solution to stand over night and filter through a 24 cm. folded filter paper. Test the filtrate for freedom from metals by the dithizone test described below.

B. Di-potassium phosphate or di-ammonium phosphate.—Add 65 grams of CaCO<sub>3</sub> and 25 cc. M/1 Ca(NO<sub>3</sub>)<sub>2</sub> to 5 liters of each of the molar solutions and treat as under A. The pure filtrate is acidified to pH 5.5 with the special grade H<sub>2</sub>SO<sub>4</sub> or HNO<sub>3</sub>.

C. Magnesium sulphate.—Add 65 grams of CaCO<sub>3</sub>, 50 cc. M/1 Ca(NO<sub>3</sub>)<sub>2</sub>, and 50 cc. of M/1 K<sub>2</sub>HPO<sub>4</sub> to 5 liters of a molar solution of magnesium sulphate and treat as under A.

D. Ammonium sulphate.—Treat as under C, but heat the solution for about 45 minutes in an Arnold steam chamber instead of autoclaving.

THE DITHIZONE TEST FOR TOTAL METALS.—Reagents needed: (1) Redistilled chloroform. (2) Redistilled NH<sub>4</sub>OH, approximately 6 Normal. (3) Redistilled water. (4) Redistilled HCl. (Distilled from a 6 Normal solution). (5) Dithizone reagent; dissolve 100 milligrams of diphenylthiocarbazone in 100 cc. of redistilled chloroform.-Before using the dithizone for sensitive colorimetric tests, it is desirable to purify it and also to remove such metal impurities as may adhere to the walls of the separatory funnel from previous determinations. This is carried out as follows: place 10 cc. of water and 5 cc. of chloroform (1) in the separatory funnel, add 3 drops of the dithizone dissolved in chloroform and 5 drops of the 6 N NH4OH (2). Shake vigorously and allow the chloroform layer to settle out. Remove the chloroform layer and save the dithizone contained in the ammoniacal water for the subsequent test to be made in the same separatory funnel.—(6) Purified ammonium citrate reagent, prepared as follows: Dissolve 192 grams of C. P. citric acid in 500 cc. of distilled water. Add 150 cc. of concentrated NH4OH, cool, and add additional NH<sub>4</sub>OH to give a faint pink color with phenolphthalein. Bring the volume of the prepared ammonium citrate solution to one liter. Place 500 cc. of this solution in a oneliter separatory funnel. Add 10 mg. of dithizone and 10 cc. of chloroform (1) and shake. Draw off the chloroform layer, add 10 cc. of chloroform (1) and 2 mg. portions of dithizone until enough dithizone has been added to maintain a straw-yellow color in the aqueous layer, after the solution is shaken. If the ammonium citrate solution is free from metals, the aqueous layer will be straw-yellow in color and the chloroform layer green. If a reddish coloration, indicating the presence of metals, is observed in the chloroform layer, draw off the chloroform layer again. Continue adding dithizone and extracting with chloroform until the ammonium citrate solution is free from metals as indicated by absence of any reddish tinge in the green chloroform layer.

DIRECTIONS FOR TESTING THE PURITY OF WATER. -Place 200 cc. of the water to be tested and 5 cc. of chloroform in the separatory funnel containing purified dithizone (5), shake vigorously for a minute or more, and then allow the chloroform layer to settle out. A red or purple color in the chloroform layer indicates the presence of one or more of the following metals: zinc, copper, lead, nickel, cobalt, mercury, cadmium, thallium, and bismuth. Quantitative estimates are made by comparing with standards prepared by adding known amounts of metals to pure water and treating the solution in the same manner. Known amounts of zinc were generally used in the preparation of standards. If less than 0.2 y of metals (by comparison with a zinc standard) is found in the 200 cc. sample, the water is designated as containing less than one part per billion of metals. The actual metal content may be estimated more accurately by testing a larger sample of water.

DIRECTIONS FOR TESTING THE PURITY OF MOLAR STOCK SOLUTIONS.—Molar stock solutions of all salts were approved for use if found to contain less than 10 parts per billion of metal impurities. This degree of purity was usually attained after one purification. In certain cases, with heavily con-

taminated salts, a second treatment was necessary. In such cases the filtrate obtained after the first purification was treated as the original stock solution. Directions for testing the various salts are given below:

A. Calcium nitrate, potassium nitrate, or dipotassium phosphate.—Place 50 cc. of the purified molar salt solution and 100 cc. of the tested redistilled water in the separatory funnel containing the purified dithizone (5), add 5 cc. of chloroform. shake vigorously for a minute or more, and allow the chloroform layer to settle out. A red or purple color in the chloroform layer indicates the presence of one or more of the metals previously listed. Estimate the amount of metals present by comparing the color of the chloroform layer with that of a standard, prepared by adding a known amount of a metal (zinc sulphate) to pure water and extracting with dithizone and chloroform as described above. If less than 0.5 gammas of metals is found in 50 cc. of molar salt solutions (corresponding to less than 10 parts per billion), the salt is approved for use.

B. Di-ammonium phosphate or ammonium sulphate.—In the presence of ammonium salts, dithizone is slightly soluble in the chloroform layer and imparts to it a green color which masks the usual red of the metal-dithizone complexes. It is therefore necessary after proceeding as in A to remove the green color by withdrawing the chloroform layer to another separatory funnel containing 50 cc. of tested water and 2 drops of NH<sub>4</sub>OH (2), shaking, and allowing the chloroform layer to settle out. Compare the now apparent red color of the dithizone metal complexes which remain in the chloroform layer with a standard as in A.

C. Magnesium sulphate. - Add 5 cc. of the purified ammonium citrate reagent (6) to the separatory funnel containing the purified dithizone and proceed as under B. The ammonium citrate prevents the formation of magnesium phosphate in the alkaline solution. Since ammonium salts have been added, a green color appears in the chloroform layer which is removed as in the test for ammonium phosphate or sulphate.

EXPERIMENTS WITH PLANTS.—Biological confirmation of the efficacy of the purification procedures described above was obtained from experiments with tomato plants. Plants of the Crackerjack (Earliana) variety were germinated in pure acid-washed sand and transplanted into 2-liter Pyrex beakers filled with nutrient solution. Eight plants were grown in each beaker. The composition of the nutrient solution, including the solutions A4 and B7 of supplementary microelements, was previously described (Arnon, 1938).

The complete list of microelements furnished by the A4 and B7 solutions consisted of boron, manganese, zinc, copper, molybdenum, vanadium, titanium, tungsten, chromium, nickel, and cobalt. To produce deficiency symptoms of manganese, zinc,

and copper, each of these three elements, respectively, was omitted from the complete list.

The importance of purification of water and chemicals was tested by growing plants in four series of nutrient solutions prepared as follows: (1) Ordinary distilled water and unpurified salts; (2) ordinary distilled water and purified salts;

(3) redistilled water and unpurified salts; (4) redistilled water and purified salts.

Duplicate cultures of each of the four treatments -complete, minus zinc, minus manganese, and minus copper-were used in each series, giving a total of 32 cultures.

Plants were set out in the nutrient solutions on April 11. After three weeks plants growing in the minus manganese nutrient solutions made with purified salts (series 2 and 4) developed characteristic manganese deficiency symptoms (Schreiner and Dawson, 1927). These symptoms in tomato plants bear a marked resemblance to "frenching" symptoms in tung trees, also traceable to manganese deficiency (Reuther and Dickey, 1937).

The development of manganese deficiency symptoms was confined to cultures in series 2 and 4, in which purified salts were used with distilled and redistilled water, respectively. If unpurified salts were used (series 1 and 3), no manganese deficiency symptoms were observed, whether distilled or redistilled water was used (table 2). It was evident that the unpurified salts, and not the distilled water, formed the important source of manganese impurities.

Different results were obtained with the minuszinc and minus-copper cultures. Characteristic zinc and copper deficiency symptoms (Reed, 1939) were found in three weeks old plants of series 3 and 4, in which redistilled water was used, with unpurified and purified salts, respectively, but not in series 1 and 2, in which distilled water was used The important source of copper and zinc contamination was the distilled water and not the unpurified salts. With redistilled water it was possible to produce at early growth stages copper and zinc deficiency symptoms even when unpurified salts were used in the preparation of nutrient solutions. However, an earlier onset and a greater severity of deficiency symptoms was evident in series 4 (redistilled water and purified salts), indicating that the unpurified salts were yielding some zinc and copper impurities to the solutions but in amounts not adequate for the needs of the plant.

As the plants increased in size, zinc and copper deficiency symptoms gradually developed in cultures with ordinary distilled water (series 1 and 2), suggesting that the impurities derived from this source became inadequate in supplying the increasing requirements of the plants. Manganese deficiency symptoms have likewise developed with time in minus manganese cultures, in series 1 and 3 in which unpurified salts were employed in the preparation of nutrient solutions.

Table 2. Average dry weights in grams of young tomato plants (8) grown in complete and deficient nutrient solutions of varied purity.

	Comp	Complete		Minus copper		Minus zinc		Minus manganese	
Series	Shoot	Root	Shoot	Root	Shoot	Root	Shoot	Root	
1. Distilled water Unpurified salts	} 2.6	0.90	2.7	0.85	2.0	0.75	2.4	0.85	
2. Distilled water Purified salts	∵} 2.9	0.90	2.5	0.85	1.2	0.75	1.8	0.50	
3. Redistilled water Unpurified salts	$\left. \begin{array}{c} \cdot \cdot \\ \cdot \cdot \\ \end{array} \right\} \;\; 2.9$	0.85	1.8	0.65	0.75	0.55	2.4	0.95	
4. Redistilled water Purified salts	•	0.95	1.1	0.55	0.45	0.55	1.7	0.50	

These and other findings not included in this report, showed that consistent demonstrations of early deficiency symptoms of zinc, copper, and manganese at all seasons of the year were possible only if redistilled water and purified salts were used. But if tomato plants were grown to relatively large size in cultures deficient in one of the three metals, deficiency symptoms were produced at times without resorting to any or with only partial purification of the nutrient medium.

The plants in the complete nutrient solutions grew equally well in the 4 series. The dry weights of plants grown for five weeks in the various nutrient solutions are given in table 2. The reduced weights of roots and shoots in the different series reflect the impairment of growth as a consequence of a particular deficiency and provide a relative measure of the importance of purification procedures for the several elements. In other experiments, by allowing the plants to grow longer, more striking differences were shown between the complete and deficient cultures, as a result of the continuously favorable growth of the former and the decline and necrosis of the latter.

The observed development of copper, manganese, and zinc deficiency symptoms were not only wholly prevented by the inclusion of these elements in the culture medium (in concentrations of 0.02, 0.5, and 0.05 ppm., respectively), but recovery and resumption of normal growth was effected by spraying the deficient cultures with dilute solutions of the elements concerned. This provided direct proof of the specific and direct relation of these elements to the nutrition of the plant quite apart from their possible effects on root environment (Arnon and Stout, 1939).

Discussion.—The results demonstrated the desirability of rigid purification of the nutrient medium for investigations on the relation of microelements to plant nutrition. The amounts of contaminants derived from containers, distilled water, and C. P. salts varied greatly and at times supplied in full plant requirements for a given microelement.

The purification procedures described give an effective and comparatively simple method for

preparation of large volumes of nutrient solutions relatively free from heavy metal impurities. The suitability of this technique for investigations on the rôle of certain microelements in the nutrition of higher plants is indicated by the fact that consistent responses were obtained from adding small amounts of zinc, copper, manganese, and certain other heavy metals such as molybdenum to deficient cultures prepared with redistilled water and purified salts. Attention is called, however, to the unsuitability of these purified salts for producing deficiencies of "macro-elements" since small amounts of calcium, potassium, nitrogen and phosphorus are incorporated in the molar stock solutions in the purification process.

The use of the sensitive dithizone test for the analytical determination of metal contaminants was distinctly helpful. It offered a means of quantitative estimation of the purity of the individual constituents of the nutrient medium before undertaking qualitative biological tests for producing deficiency symptoms in a growing plant and made it possible to prepare in Pyrex containers nutrient solutions of equal and reproducible purity.

The minute requirement of plants for elements like copper endows them in a sense with the power to serve as biological indicators for the presence of minute amounts of certain metals in distilled water or in chemicals. In the present investigation for example, distilled water alone, derived from a usual laboratory still (tin-lined copper) was found at times to supply enough copper for the growth of young tomato plants.

A distinction must be made between chemical and biological purity of water and chemicals. It is clear, considering the minute requirements of plants, that purity of chemicals, in the usual analytical sense, expressed generally in terms of percentages of impurities present, may be quite meaningless, if freedom from microelements is considered. The value of a preliminary chemical analysis of all constituents of the nutrient medium as by spectrographic means (Chapman, Vanselow, and Liebig, 1937) is evident.

The special importance of a suitable experimental technique in research on microelements adds weight to positive findings which show plant responses to addition of minute amounts of certain elements. A subsequent failure to repeat such results may mean, in the absence of evidence to the contrary, that either the culture medium became contaminated or that an impurity was added through the aerial portions of the plant. It would seem best, in experiments with metals determinable by the dithizone test, to find analytically the upper limit of impurity that may be present in the culture medium and to express the results of experiments on a quantitative basis—that is, that with a certain upper limit of supply, a given response is obtained with certain species of plants. A further discussion of this viewpoint is presented elsewhere (Arnon and Stout, 1939).

#### SUMMARY

An experimental water-culture technique adapted to ordinary laboratory and greenhouse facilities for investigating the physiological importance of zinc, manganese, and copper in the nutrition of higher plants is described.

Reed, H. S. 1939. The relation of copper and zinc salts to leaf structure. Amer. Jour. Bot. 26: 29-33.

The technique involves (a) the selection of suitable containers, (b) purification of water by redistillation, using a Pyrex glass condenser, and (c) purification of molar stock solutions of individual nutrient salts. Adaptations of Steinberg's calcium carbonate procedure for purifying the nutrient solution as a whole were devised for the purification of the relatively concentrated molar stock solutions of individual nutrient salts.

The purity of water and each individual molar stock solution of nutrient salts is tested prior to use by means of a specially adapted dithizone test. By using Pyrex glass containers and tested water and salts, nutrient media of reproducible purity were prepared at all times.

Biological confirmation of the purity of nutrient medium was obtained by growing plants in nutrient solutions deficient in manganese, zinc, and copper, respectively. Plants consistently developed early deficiency symptoms characteristic of each element.

# FURTHER EXPERIMENTS ON EXCISED TOMATO ROOTS 1

William J. Robbins and Mary Bartley Schmidt

We reported previously (1937a, 1937b, 1938) that excised tomato roots require for unlimited growth an external supply of thiamin (vitamin  $B_1$ ) or the vitamin thiazole (4-methyl-5- $\beta$ hydroxy-ethyl thiazole), in addition to sugar, mineral salts, and water. We have maintained excised tomato roots in a solution of mineral salts, pure cane sugar, and thiamin through 25 successive passages extending over a period of more than two years. In this solution the average growth in a period of two months of a single root rarely exceeds 10 mg. and is usually less. However, when a light brown sugar is

<sup>1</sup> Received for publication January 19, 1939. Supported in part by a grant from the American Philosophical Society. substituted for the pure cane sugar in the solution given above, the growth is much improved, the average dry weight of individual roots reaching 70 or 80 mg. (fig. 1).

Why is the brown sugar beneficial? We believe that it is in part because of the minerals contained in the sugar, but primarily because of the presence of vitamin B<sub>6</sub>. We present evidence in this paper that in the presence of thiamin this portion of the B complex has a marked beneficial effect upon the growth of excised tomato roots (see also Robbins and Schmidt, 1939).

METHODS AND MATERIALS.—The methods used in this investigation are similar to those described earlier (Robbins and Schmidt, 1938). Excised to-

mato roots were grown individually in 50 ml. of solution in 125 ml. Erlenmeyer flasks of Pyrex glass. The roots came originally from seeds of a pink fruited variety of *Lycopersicon esculentum* from Mexico. The excised roots have been kept in cultivation since September 29, 1935. They represent two clones which respond alike.

The nutrient solutions used had the following

composition per liter:

White's mineral solution: Ca(NO<sub>3</sub>)<sub>2</sub>, 0.142 g.; MgSO<sub>4</sub>7 H<sub>2</sub>O, 0.073 g.; KNO<sub>3</sub>, 0.081 g.; KCl 0.065 g.; KH<sub>2</sub>PO<sub>4</sub>, 0.012 g.; Fe<sub>2</sub>(SO<sub>4</sub>)<sub>3</sub>, 0.0024 g.

Pfeffer's mineral solution (modified): Ca(NO<sub>3</sub>)<sub>2</sub>, 0.333 g.; MgSO<sub>4</sub>7 H<sub>2</sub>O, 0.063 g.; KNO<sub>3</sub>, 0.063 g.;

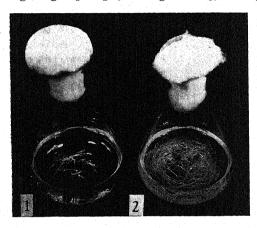

Fig. 1. Effect of light brown sugar. 1, root grown in Pfeffer's solution plus  $10\,\gamma$  of thiamin and 2 per cent pure cane sugar; 2, in same solution with 2 per cent light brown sugar instead of pure cane sugar. Age about 2 months.

KCl, 0.042 g.;  $KH_2PO_4$ , 0.060 g.;  $Fe_2(SO_4)_3$ , 0.0025 g.

Mineral solution W: White's mineral solution

plus 0.1 ppm. each of zinc and of boron.

The mineral salts were of chemically pure grade and not especially purified. The cane sugar was Pfanstiehl's C. P. sucrose. The thiamin was Merck's synthetic vitamin  $B_1$  (Betabion). The solutions were sterilized in an autoclave at 10 or 15 pounds steam pressure. The roots were grown in diffuse light at temperatures ranging from  $20^{\circ}$  to  $25^{\circ}$ C.

EXPERIMENTAL RESULTS.—Effect of brown sugar.

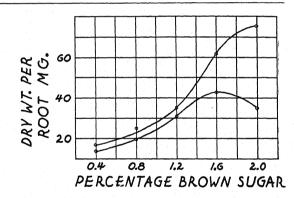

—The beneficial effect of brown sugar as compared with pure cane sugar was reported earlier (Robbins and Schmidt, 1938). We have used six samples of light brown sugar and have found all of them beneficial, though not equally so. The growth of the excised roots in White's mineral solution or Pfeffer's mineral solution plus 2 per cent brown sugar and thiamin is slow in starting, and the roots are long, white, with short, sparse root hairs. Growth continues for three months or more, and individual roots weighing 165.0 mg. have been obtained. Dark brown sugars at 2 per cent are sufficiently injurious

to inhibit growth entirely. In fact the light brown sugars also at 2 per cent concentration are somewhat injurious, causing, as we believe, the slow starting of growth and the partial inhibition of growth of some roots noted in several instances.

Dilution of brown sugar.—When the light brown sugars are diluted, the total growth is decreased, as illustrated in the following experiment: White's mineral solution plus 2 per cent light brown sugar No. 5 and 0.2 ppm. of thiamin was diluted with White's mineral solution plus 2 per cent pure cane sugar and 0.2 ppm. of thiamin to produce solutions

Table 1. Effect of dilution of light brown sugar in White's mineral solution, sugar, and  $10\,\gamma$  thiamin per flask on growth of excised tomato roots. Roots grown two months at  $20^\circ-25$  C. Total concentration of sugar maintained at 2 per cent by addition of pure cane sugar. Passage 33.

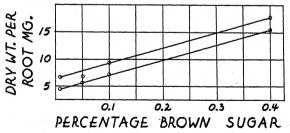

Fig. 2 (above). Effect on growth of excised tomato roots of dilution of light brown sugar, total concentration of sugar 2 per cent by addition of pure cane sugar. Lower curve average of 5 roots, upper curve, average of 2 best roots. Age about 2 months.

Fig. 3 (below). Effect on growth of excised tomato roots of dilution of two samples of light brown sugar. Total concentration of sugar 2 per cent by addition of pure cane sugar. Age about 2 months.

containing 2, 1.6, 1.2, 0.8, 0.4 per cent, and no light brown sugar. The total concentration of sugar in each of these solutions was 2 per cent. Five replications for each solution were used in the experiment which was run for two months. The results are presented in table 1 and figure 2.

When the average of all the roots grown at a particular concentration is considered, the optimum for this sample of brown sugar was 1.6 per cent. This is because of the greater variation in growth at the higher concentrations of brown sugar where some injurious factor or factors (probably the ash) inhibited some of the root tips. If the average of the two best roots is considered, a dilution of the sugar to 1.6 per cent decreased the growth. This suggests that the amount of the beneficial factor or factors in the 2 per cent light brown sugar does not exceed the optimum.

Dilution of the brown sugar below 0.4 per cent reduced growth further, as is shown in table 2 and

Table 2. Effect of dilution of two samples of light brown sugar in White's mineral solution plus  $10\gamma$  of thiamin per flask. Roots grown two months at  $20^{\circ}-25$  C. Total concentration of sugar maintained at 2 per cent by addition of pure cane sugar. Passage 33.

figure 3. Two samples of brown sugar were used in this experiment, No. 5 and No. 6, and each was used at 0.4, 0.1, 0.5, and 0.01 per cent; the total concentration of sugar was made 2 per cent by the addition of pure cane sugar. From the data in table 2 and the curves in figure 3, sample No. 6 appears to contain more of the beneficial material than sample No. 5. The relation between amount of brown sugar and growth at these greater dilutions was linear.

Effect of ash of light brown sugar.—In discussing the highly beneficial effect of the light brown sugar, we reported (1938) that its ash, in amounts equivalent to that in a 2 per cent solution of the sugar, proved toxic but suggested that smaller amounts of the ash might be beneficial. The possibility that the favorable action of the brown sugar might be associated with the minerals it contains has been investigated further, but we have been unable to demonstrate that the ash produces more than a minor benefit. Furthermore, the growth of tomato

roots in 2 per cent light brown sugar and thiamin to which no mineral salts were added was slight in spite of the relatively high ash content of the sugar. This is probably because of a deficiency of nitrates.

Pfeffer's mineral solution plus 2 per cent pure cane sugar and 10 y of thiamin per flask was supplemented with amounts of the ash of light brown sugar equivalent to that contained in 2, 1, 0.4, and 0.2 per cent solutions of the sugar. This experiment was repeated using ash which had been treated with HCl. To 160 mg. of the ash 10 ml. of HCl were added and heated to dryness, the procedure was repeated, and the residue taken up in water. Little benefit was observed from the untreated ash at any of the concentrations (table 3). In fact at an amount equivalent to that in a 2 per cent solution of sugar the ash inhibited growth entirely and was somewhat injurious at one-half that strength. Some benefit was derived from the treated ash at concentrations equivalent to the ash in 1, 0.4, and 0.2 per cent sugar solutions, the most favorable result appearing at 0.4 per cent. However, even here the growth was much less than that obtained with brown sugar. It is recognized that some minerals are volatilized to a greater or less extent in the ashing and some are changed in form. We are not certain whether the treated ash was more favorable than the untreated ash because of further volatilization of some elements, because the HCl brought some beneficial elements into solution, or because something was added in the HCl used in the digestion. In any event, the experiments with the ash of brown sugar did not encourage us to look there for the favorable factor of primary importance. We therefore turned our attention to the organic constituents of the impure sugar.

Again, as in our investigation which resulted in our discovery of the importance of thiamin for the growth of excised tomato roots, there were two obvious means of approach to this problem. One was to fractionate the sugar in various ways to find some clue to the favorable factor or factors, the other was to try as many suspected substances as might be available. Both procedures were followed.

Extraction of light brown sugar.—Attempts to extract the beneficial material by the use of various solvents and adsorption on "decalso" were not particularly successful. In several instances some benefit resulted from the addition of the extracts to Pfeffer's solution containing pure cane sugar and thiamin, but in none was the growth comparable to that in solutions containing the light brown sugar. It would doubtless be entirely possible to prepare extracts which contained the beneficial materials, but time and facilities limited our efforts in that direction.

A number of substances including heteroauxin, lactoflavin, cysteine hydrochloride, and pimelic acid were previously used to supplement a mineral solution containing cane sugar and thiamin (Robbins and Schmidt, 1938). None of them, as we used

them, improved the growth of excised tomato roots. In addition, we have tried nicotinic acid, nicotinamide, amino acids, and vitamin  $B_6$ .

Nicotinic acid and nicotinamide.—Knight (1937a, 1937b) found nicotinic acid or nicotinamide necessary for the growth of Staphylococcus aureus. We found excised tomato roots made little growth in Pfeffer's mineral solution plus 2 per cent pure cane sugar and  $10 \gamma$  per flask of nicotinic acid or nicotinamide. The growth in the same solutions to which  $10 \gamma$  of thiamin per flask were added was about the same as that in the Pfeffer's solution plus cane sugar and thiamin alone. We concluded that nicotinic acid or nicotinamide did not substitute for thiamin in the growth of tomato roots and was not the factor chiefly responsible for the favorable action of brown sugar.

Amino acids.—White (1937a, 1937b) in studies of the separation from yeast of materials essential for the growth of excised tomato roots concluded that an important part of the yeast fraction soluble in 85 per cent alcohol was amino acids. He prepared a mixture of amino acids which when added to a solution of sugar and mineral salts exerted a favorable effect on the growth of the roots. When the amino acid mixture and a yeast fraction soluble in 100 per cent alcohol were used by White as supplements to a mineral salt-sugar solution, growth

. 4							

approached that in a solution supplemented with yeast. In a later paper White (1937c) concluded that thiamin was a constituent of the yeast fraction soluble in 100 per cent alcohol important for the growth of excised tomato roots.

In our experiments an absolute alcohol extract of yeast was ineffective (1937a, 1938). In fact, thiamin is extremely sparingly soluble in neutral absolute alcohol and is not extracted from yeast and food stuffs by this solvent unless an excess of mineral acid is present (Williams, 1937). Furthermore, we have been unable to detect a favorable effect of White's amino acid mixture on the growth of our strain of tomato roots in a mineral-sugar solution, or in a mineral-sugar solution supplemented with thiamin.

The provisional amino acid mixture per liter given by White as "complete and possibly optimal" and the source of our amino acids were as follows: 5 mg. d- glutamic acid, Eastman; 1.5 mg. dl- phenyl alanine, Marvel; 1.5 mg. dl- lysine, Marvel; 1.5 mg. l- histidine, Eastman; 1.5 mg. l- proline, Pfanstiehl; 0.15 mg. dl- valine, Marvel; 0.05 mg. dl-serine, Pfanstiehl; 0.015 mg. dl-norleucine, Marvel; 0.0015 mg. dl-isoleucine, Marvel.

In our experiments the addition of this mixture of amino acids to White's mineral solution plus 2 per cent sugar and  $10\,\gamma$  of thiamin per flask had no effect (table 4), nor was any effect noted when mineral solution W plus cane sugar and thiamin was used. The addition of the amino acid mixture to these solutions was not injurious, the roots grew, but grew as well without the amino acids as with them. No growth was secured in mineral solution W plus 2 per cent cane sugar and the amino acid mixture. The amino acid mixture was not found to substitute for nitrates. When the nitrates in White's solution were replaced with the amino acid mixture at the concentration given or at 5 times that strength, no growth occurred.

We concluded that under the conditions of our experiments the amino acid mixture was of no significant benefit and that the beneficial effect of light brown sugar could not be credited to its possible amino acid content. Bonner and Addicott

(1937) reported amino acids to be beneficial to the growth of excised pea roots. Pea roots and the strain of tomato roots used by White may respond differently from the roots we have used. We recognize also that amino acids may prove beneficial to the growth of our strain of tomato roots when other limiting factors have been removed. However, the roots we have used were capable of constructing the necessary proteins from nitrates, as is evidenced from the results of our experiments in which nitrates have been the sole source of nitrogen.

Vitamin  $B_6$ .—Emerson, Mohammad, Emerson, and Evans (1938) reported that molasses is rich in vitamin  $B_6$ . Although this vitamin has not hitherto been demonstrated to be important in plant growth, its presence in molasses and its probable presence in brown sugar suggested its use. Kuhn and Went (1938), Lepovsky (1938), and Keresztesy and Stevens (1938) reported its isolation in crystalline form. Through the courtesy of Merck and Co., a sample of crystalline vitamin  $B_6$  isolated from natural sources was secured. Its empirical formula

as given by Merck and Co. is  $C_8H_{11}NO_3$ .HCl. Vitamin  $B_6$  produced a marked increase in the growth of excised tomato roots when added to a solution of mineral salts, pure cane sugar, and thiamin. In fact, the growth in mineral-sugar solutions supplemented with both thiamin and vitamin  $B_6$  materially surpassed that in a mineral-sugar-yeast solution. Furthermore, the addition of vitamin  $B_6$  to diluted light brown sugar solutions supplemented with thiamin markedly increased the growth, demonstrating that in such solutions vitamin  $B_6$  was the limiting factor.

In the first experiment with vitamin  $B_6$  the excised roots were grown for two months in Pfeffer's solution containing 2 per cent pure cane sugar supplemented with thiamin, vitamin  $B_6$ , and light brown sugar ash, which had been treated with HCl. The ash was used at a concentration equivalent to that in a 0.4 per cent sugar solution. Thiamin was added at the rate of 5  $\gamma$  per flask, and vitamin  $B_6$  at 1  $\gamma$  and 5  $\gamma$  per flask (table 5). Vitamin  $B_6$  used alone in Pfeffer's solution containing pure cane

sugar had little effect on growth,2 but in the presence of thiamin the benefit was noticeable within the first week of growth. The roots in the solutions containing thiamin and vitamin B6 grew more rapidly than in the solutions supplemented with thiamin alone and developed a particularly luxuriant crop of root hairs. The growth was more rapid in the solutions supplemented with thiamin and 5 y of vitamin B<sub>6</sub> than in those supplemented with thiamin and 1 y of B6, although the final dry weights (table 5) taken at the end of two months did not show this difference except where the solution contained the light brown sugar ash. Evidently some factor, probably the mineral supply, limited the total growth in the Pfeffer's solution not supplemented with ash. At any rate, the growth in the solutions containing thiamin and vitamin B6 was several times that in the solutions containing thiamin only.

Amount of vitamin B<sub>6</sub> and growth.—In the early stages of the above experiment the roots grew more rapidly in those solutions containing 5  $\gamma$  of vitamin B<sub>6</sub> than in those containing 1 γ, though the difference in growth (except where ash was added also) did not appear in the final dry weights. Two experiments were performed with various amounts of vitamin B<sub>6</sub> per flask. In the first, amounts from 0.000 000 1 y to 10 y per flask in multiples of ten were added to Pfeffer's solution containing 2 per cent pure cane sugar and 10 y of thiamin per flask. The roots were grown for two months. No benefit was noted from the addition of amounts of vitamin  $B_6$  from 0.000 000 1  $\gamma$  up to and including 0.1  $\gamma$  per flask. The final growth with  $1 \gamma$  of vitamin  $B_6$  was about one and one-half times the growth in the Pfeffer's solution supplemented with thiamin alone, and with 10 y of B<sub>6</sub> per flask over twice as much growth was obtained.

Since there was some evidence that  $10 \gamma$  of vitamin  $B_6$  per flask was superior to  $1 \gamma$ , a second experiment was performed in which  $10 \gamma$ ,  $50 \gamma$ , and  $100 \gamma$  per flask were added to Pfeffer's solution con-

 $^2$  One root grew considerably (8.4 mg.) in the solution containing 1  $\gamma$  of vitamin  $B_6$ ; none of the others grew appreciably. We believe that sufficient thiamin was contained in the root tip to permit the growth noted, or an error in experimental procedure was responsible for this result.

taining 2 per cent pure cane sugar and 0.2 ppm. of thiamin. The roots grew more rapidly in the solutions containing  $50 \gamma$  per flask than in those containing  $10 \gamma$  or  $100 \gamma$ .

During the second week of growth, sketches were made at regular intervals of the main tip of one root in the solutions containing 50 y of vitamin B<sub>6</sub> per flask. It was found to be growing at the rate of between 0.75 cm. and 1.0 cm. per 24 hours. Fifteen days after the initiation of the experiment, growth of this tip ceased. Final dry weights were determined at the end of two months (table 6). Growth was greater in the solutions containing 50  $\gamma$  of vitamin B<sub>6</sub> than in those containing 10  $\gamma$ or 100 y. However, in this experiment the growth with 10 y was no better than in the earlier experiment with 1 y. If dry weights had been determined at the end of two or three weeks, greater differences in growth with various amounts of vitamin B<sub>6</sub> would probably have been found. It would seem that greater amounts of vitamin B6 than of thiamin are necessary in the growth of tomato roots, as responses have been secured to thiamin at amounts which were ineffective when vitamin B<sub>6</sub> was used.

Mention has already been made of the profuse root hair production in solutions containing vitamin  $B_6$ . It was observed also that in the vitamin  $B_6$  solutions portions of many of the roots eventually developed a chocolate brown color. Furthermore, a development of hooks and curls by the root tips was observed in solutions containing vitamin  $B_6$ , a condition which we have never noted in any other solution.

Growth abnormalities in solutions containing vitamin  $B_6$ .—The tomato roots in the solutions supplemented with vitamin  $B_6$  grew more rapidly than those in the solutions lacking the vitamin. However, many of the main root tips and many branch ends developed hooks, curls, and corkscrews after ten days or two weeks of growth. It was thought this might be a response to the exposure to light, and the roots were transferred to a darkened chamber where the condition disappeared.

However, we doubt whether light was concerned, as roots grown in the presence of vitamin  $B_6$  in a darkened chamber developed similar abnormalities which disappeared in time. Quintuplicate cultures were prepared in Pfeffer's solution containing 2 per

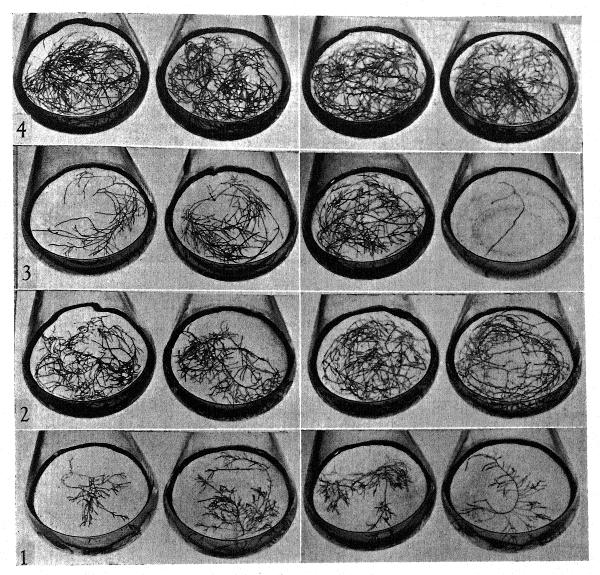

Fig. 5. Effect on growth of excised tomato roots of addition of vitamin  $B_6$  to dilute light brown sugar. 1, growth in Pfeffer's solution plus 0.4 per cent light brown sugar, 1.6 per cent pure cane sugar and 0.2 ppm. thiamin; 2, same plus  $10 \gamma$  vitamin  $B_6$  per flask; 3, in Pfeffer's solution plus 1.2 per cent light brown sugar, 0.8 per cent pure cane sugar and 0.2 ppm. thiamin; 4, same plus  $10 \gamma$  vitamin  $B_6$  per flask. Age about 2 months.

cent pure cane sugar and 0.2 ppm. of thiamin, 2 per cent pure cane sugar plus 0.2 ppm. of thiamin and 0.2 ppm. of vitamin  $B_6$  and set in the light. A similar set was placed in a dark box. This procedure was repeated with the pure cane sugar replaced by 0.4 per cent light brown sugar and 1.6 per cent pure cane sugar. The ends of branches of the roots in the solutions containing vitamin  $B_6$  developed curls and hooks, both in the light and in the dark. After about three weeks the hooks and curls were less noticeable. It appeared that the hooks and curls developed in response to the vitamin  $B_6$ , and that light was not concerned, though of course the roots in the darkened chamber were exposed to light when

examined at intervals, and we cannot say that light was entirely excluded.

Microscopic examination<sup>3</sup> of some of the curled roots demonstrated that the bending was the result of a failure of the cells on one side of the root to elongate. The cells on the concave side of a curve were about the same length as those near the apical meristem; the length of those on the convex side averaged about 5 times that of those on the concave side. Branch roots developed on the convex side of the curve, and it appeared from the observations made that with the initiation of a branch root the cells on the concave side of the curve lengthened,

<sup>3</sup> These microscopic studies were made with the assistance of Dr. Virgene W. Kavanagh.

with the result that the sharp curve disappeared, the root tending to straighten out.

Although these observations are incomplete and fragmentary, they suggest that excised tomato roots grow so rapidly in solutions containing both thiamin and vitamin B<sub>6</sub> that some substance necessary for the lengthening of the cells in the region of elongation comes near exhaustion. With the exhaustion of this material, elongation is reduced, and new quantities of the material formed in the root are unequally distributed, resulting in the formation of hooks, curls, and corkscrews. If these assumptions are correct, the substance concerned would not be thiamin, vitamin B6, or nicotinamide, since we have noted the development of these abnormalities in a solution supplemented with all three of these substances. What the material concerned is, where it is produced in the root, and why it is unequally distributed, are obvious unanswered questions.

Addition of vitamin  $B_6$  to dilute light brown sugar.—If the beneficial effect of the light brown sugar is chiefly because of its vitamin  $B_6$  content, then the decreased growth noted when the sugar was diluted, as described above, might be assumed to result from the decreased amount of vitamin  $B_6$  available. The addition of vitamin  $B_6$  to such dilute brown sugar solutions should increase the growth. We have found that this occurred.

Pfeffer's solution containing 2 per cent light brown sugar and 0.2 ppm. of thiamin was mixed with Pfeffer's solution containing 2 per cent pure cane sugar and 0.2 ppm. of thiamin to produce solutions with 0.4 per cent and 1.2 per cent light brown sugar, respectively. To some of the flasks  $10 \gamma$  of vitamin  $B_6$  were added. The growth in the solutions containing dilute brown sugar supplemented with vitamin  $B_6$  (table 7) approached that in the 2 per cent light brown sugar (table 1) which supported the conclusion that vitamin  $B_6$  was the factor primarily responsible for the beneficial effect of light brown sugar as compared to pure cane sugar.

We are of the opinion that factors other than vitamin  $B_6$  (the minerals and perhaps other growth substances) play a part in determining the beneficial action of the brown sugar. This follows because the growth in Pfeffer's solution containing 2 per cent pure sugar, thiamin, and vitamin  $B_6$ , was not as great as that in the same solution in which part of the sugar was supplied as light brown sugar.

This opinion is supported also by the difference in the growth of root tips from a solution of minerals, maltose, and yeast and those from a solution of minerals, cane sugar, and thiazole, when both are grown in solutions containing thiamin and vitamin B<sub>6</sub>. We have previously reported that some samples of maltose are more beneficial for the growth of excised tomato roots than pure cane sugar, and we were of the opinion that the difference in the effects of the two sugars was because of impurities in the maltose. Stock cultures of tomato roots in White's or Pfeffer's mineral solution plus 2 per cent maltose and yeast have been maintained as a common source of inoculum in our experiments. However, the growth of root tips from a maltose solution was found to be considerably superior to the growth of tips from roots which had been maintained for many passages in a solution of minerals, sugar, and thiazole. Since the solutions in which this difference in growth was noted contained thiamin, vitamin B<sub>6</sub>, and nicotinamide, it seemed justifiable to assume that something other than these substances was carried over in the root fragment used as inoculum and was responsible for the difference in growth. Further investigations are necessary to determine whether the "carryover" effect from the maltose solutions was due to an unknown growth substance and, if so, the nature of the sub-

These general statements are illustrated by the following experiment:

To Pfeffer's solution containing 2 per cent of cane sugar and mineral supplements we added (1)  $10 \gamma$  of thiamin per flask; (2)  $10 \gamma$  of thiamin and  $10 \gamma$  vitamin  $B_6$ ; (3)  $10 \gamma$  thiamin and  $10 \gamma$  nicotinamide; (4)  $10 \gamma$  thiamin,  $10 \gamma$  vitamin  $B_6$ , and  $10 \gamma$  nicotinamide; (5)  $10 \gamma$  vitamin  $B_6$  and  $10 \gamma$  nicotinamide. Flasks were inoculated in quintuplicate with inoculum from roots grown in Pfeffer's solution plus yeast and 2 per cent maltose. The experiment was repeated using inoculum from roots which had grown through 19 successive passages in Pfeffer's solution plus thiazole and 2 per cent cane sugar.

The dry weights of the roots at the end of one month are given in table 8. For both types of inoculum the necessity of thiamin for growth was shown by the lack of development in solutions con-

<sup>4</sup> The mineral supplements included 0.01 ppm. B, 0.02 ppm. Mo, 0.18 ppm. Zn, 0.04 ppm. Cu and 0.02 ppm. Mn.

Table 7. Effect of addition of 10 γ vitamin B<sub>6</sub> per flask on growth of roots in Pfeffer's solution containing mixtures of light brown sugar and pure sugar plus 0.2 ppm. thiamin. Total concentration of sugar 2 per cent. Grown two months. Passage 34. Compare with

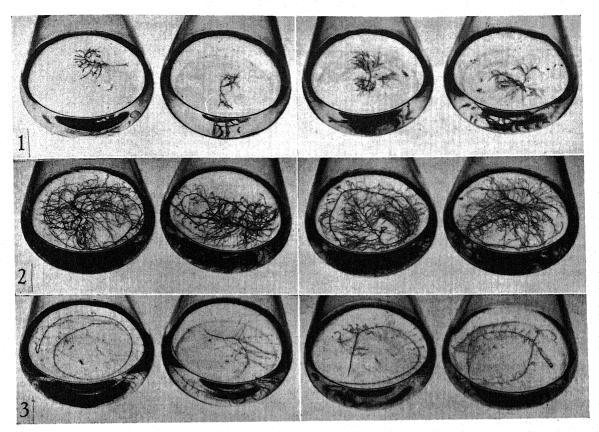

Fig. 6. Source of inoculum and effect of vitamin  $B_6$ . 1, growth in Pfeffer's solution plus 2 per cent cane sugar and 0.2 ppm. thiamin; 2 and 3, in some solution plus  $10\,\gamma$  vitamin  $B_6$  per flask. 1 and 2 inoculated with fragments of roots grown in Pfeffer's solution containing maltose and yeast; 3, inoculated with fragments of roots grown in Pfeffer's solution containing cane sugar and thiazole. Age 3 weeks.

taining vitamin  $B_6$  and nicotinamide but no thiamin. Nicotinamide had little or no effect in the presence of thiamin or of thiamin and vitamin  $B_6$ . The roots grew in all solutions which contained thiamin, but the growth was greatly increased in those solutions which contained vitamin  $B_6$  in addition. A comparison of the growth of the fragments from the roots which had grown for several passages in a solution of minerals, sugar, and thiazole with that

of fragments from roots which had grown in a solution of minerals, maltose, and yeast shows the "carryover" effect from the maltose-yeast solutions which suggests the existence of a growth factor other than thiamin, vitamin  $B_6$ , or nicotinamide.

DISCUSSION.—We are gradually gaining a clearer picture of the nutritional requirements of tomato roots and incidentally of the importance of growth substances for the development of plants. Under

the conditions of our experiments excised tomato roots synthesize little or no thiamin from the sugar and mineral salts in the medium, chiefly because of their inability to construct the intermediate thiazole; the consequence is that the excised roots are unable to grow unless furnished with thiamin or with the vitamin thiazole (Robbins and Schmidt, 1938).

However, even when supplied with more than adequate amounts of mineral salts, sugar, and thiamin, the rapidity of growth of the roots appears to be distinctly limited by their synthesis of a second vitamin, vitamin  $B_6$ . We assume that in solutions of mineral salts, sugar, and thiamin the roots synthesize vitamin  $B_6$  in amounts sufficient to permit slow growth, but not in quantity sufficient for rapid growth. The situation is somewhat analogous to the ability of  $Pythium\ Butleri$  to form sufficient thiamin for slow growth (in certain media) and its response by increased growth to additions of thiamin (Robbins and Kavanagh, 1938).

The solution of mineral salts, sugar, and yeast which we have used for the cultivation of excised tomato roots furnishes both thiamin and vitamin  $B_6$ , and the amount of the latter is probably the factor which limits growth in a solution supplemented with yeast. This follows because the growth in a solution of mineral salts and sugar supplemented with thiamin does not exceed that in a solution supplemented with yeast, even when the thiamin is present in excess, while in a solution of mineral salts, sugar, thiamin, and vitamin  $B_6$  the growth is several times that in the yeast solutions.

The function of vitamin  $B_6$  in the plant is not known. A deficiency of this vitamin interferes with the growth of rats and causes them to develop an acrodynia type of dermatitis. It is found in wheat germ autolysate, and molasses is a rich source. It was probably first isolated from rice polishings by Ohdake in 1932 (Wiarde, 1938).

The demonstration of the importance of vitamins in the physiology of plants raises questions of nomenclature which have been discussed in part elsewhere (Robbins, 1938). Since the term vitamin was limited to animals in its original definition, and the same chemical substance may be a vitamin for one organism, a hormone for a second, and neither a vitamin nor a hormone for a third, we have preferred to use the general term, growth substance. Furthermore, the demonstration that thiamin (vitamin  $B_1$ ) is important for the normal development of plants as well as animals has led us to prefer the name thiamin to that of aneurin which emphasizes the relation of that vitamin to one aspect of its importance for animals. Similarly, since vitamin B<sub>6</sub> is important for plants as well as animals, it seems

preferable to name it from its chemical constitution, when that is known, rather than to call it "adermin" as has been initiated and thus emphasize its relation to one aspect of its function in animals (Wiarde, 1938).

These observations on the importance of vitamin Bo for the growth of tomato roots add to our ideas of the dependence of the root upon the shoot, though it would be a mistake to generalize for all roots on the basis of our findings for tomato roots. We believe that many growth substances are necessary for the normal development of an organism. Some organisms synthesize all the growth substances in amounts adequate for normal growth. Others lack the ability to make one or more than one, and the synthetic ability of one organism may be different from that of another. To conclude that the growth substances which must be supplied excised tomato roots are also those which must be supplied excised corn roots, or other roots, would be in error. Furthermore, our experiments with tomato roots have been carried on in liquid cultures where the oxygen supply is limited; we cannot be certain that the responses of roots under these conditions are identical with those of roots under normal growing conditions in the soil. It seems probable, however, that the tomato root depends upon the shoot for sugar, thiamin, and vitamin B<sub>6</sub>, and further research may add to the growth substances concerned in the development of the tomato root.

#### SUMMARY

Light brown sugar was found to be more beneficial for the growth of excised tomato roots than pure cane sugar in a solution containing sugar, minerals, and thiamin. Growth decreased as the proportion of light brown sugar in the medium was reduced. The ash of the brown sugar was not responsible for the benefit observed. Nicotinic acid, nicotinamide, and amino acids were not beneficial when added to a solution of pure sugar, minerals, and thiamin, but crystalline vitamin  $B_6$  was quite beneficial. Vitamin  $B_6$  increased growth when added to solutions of sugar, minerals, and thiamin in which the proportion of brown sugar was reduced. Observations are reported on hooks and curls which developed in roots grown in solutions containing vitamin B<sub>6</sub>; these observations are interpreted to indicate the existence of a growth substance necessary for cell elongation in roots. Evidence for an unknown growth substance in samples of maltose is presented.

# PHYSIOLOGICAL RELATIONS BETWEEN HOST AND PARASITE IN CROWN GALL—AN EXAMPLE OF BASIC BIOLOGICAL RESEARCH WITH PLANT MATERIALS <sup>1</sup>

### A. J. Riker

The botanist who undertakes studies of the cell both in health and disease has certain important opportunities. It seems fitting on this centenary of the cell theory that emphasis should be placed both on the importance of cellular pathology and on certain advantages plant materials have over animal materials for basic research in this field. Some of these advantages may be briefly listed as follows:

(1) large numbers, (2) low cost, (3) ease of experimental use, (4) satisfactory physiological variability, (5) easily induced epidemics, and (6) genetic purity of hosts through (a) selfing and (b) vegetative propagation. The last is particularly important since pathogenicity must be defined in terms of resistance or susceptibility of the host.

As an example of the opportunities offered by plant materials, I am to discuss certain points in research on atypical and pathological multiplication of cells. These investigations center about the well-known plant disease, crown gall, which is caused by the bacterium, *Phytomonas tumefaciens* (Smith and Town.) Bergey et al.

Our primary interest in this topic is to determine the means whereby the bacteria, within the host tissue, are able to stimulate the great increase both in cell size and number—i.e., hypertrophy and hyperplasia. Thus, we are in a measure continuing the work so ably carried on for a number of years by Erwin F. Smith. You will remember that he pointed out various points of analogy between this plant disease and a very important hu-

<sup>1</sup> Received for publication February 1, 1939. This paper in somewhat extended form was given December 28, 1938, at Richmond, Virginia, before Section G, A. A. A. S., in a joint session between various affiliated

Botanical Societies.

Approved for publication by the Director of the Wisconsin Agricultural Experiment Station.

man disease. However, my colleagues and I, both in our discussions and publications, are careful to avoid any such terms borrowed from medicine lest confusion arise over terminology and obscure the main point of our researches—i.e., the cause of pathological growth.

The parasitic nature of this disease does not seem to separate this research from that in which no microorganism has been found associated with pathological growth. Such growth is easily induced at will in plants by a number of physical and chemical agencies. From the standpoint of the crown gall bacteria, and various other cell stimulating microorganisms, the atypical growth induced is apparently the result of physical or chemical changes occurring in the host tissue. An analytical study of what these changes may be places work involving microorganisms on much the same basis as work where no pathogens are known. However, with microorganisms as research tools, it is possible to study their metabolism of known materials in vitro as well as in vivo. With them one can induce in the localized tissues many small but continuously operating changes which seem more difficult with non-living agencies.

Only a few of the high spots, more particularly in relation to our own work,<sup>2</sup> can be mentioned this afternoon. Detailed references to the literature are

<sup>2</sup> The research at Wisconsin is supported jointly by the International Cancer Research Foundation, the University of Wisconsin, and the Wisconsin Alumni Research Foundation. It is carried on through cooperation between Professors I. L. Baldwin, Bacteriology, B. M. Duggar, Plant Physiology, W. H. Peterson, Biochemistry, and A. J. Riker, Plant Pathology, and their various associates whose names appear on the detailed publications. Aid has been received from the University of Wisconsin W.P.A. Natural Science Research Project.

omitted because of their large number, and because most of them are readily available elsewhere.<sup>3</sup> You will doubtless be interested to know that an exten-

<sup>3</sup> For example: Levine, M. 1936. Plant tumors and their relation to cancer. Bot. Rev. 2: 439-455; Riker, A. J., and T. O. Berge. 1935. Atypical and pathological multiplication of cells approached through studies on

sion of this subject is to be considered in a symposium being arranged by Dr. B. O. Dodge on "The effect of microorganisms, their products, and other chemical agents on the production of atypical growth in higher plants." It will be held next September in New York as a part of the program of the Third International Congress for Microbiologists.

The gross appearance of crown gall may be observed from figure 1. This type of growth is caused by an enormous development of cells, both in size and in number, which apparently lack organization.

A histological examination indicates that there is both hyperplasia and hypertrophy (fig. 2). Both the gross appearance and the anatomy of crown gall have many characters strikingly similar to those found in animal tumors or cancers. These characters are so well known that they are omitted in favor of some physiological considerations.

Our problem is perhaps most easily defined by considering a drawing made over a photomicrograph (fig. 3). Here we see crown gall bacteria (a) in an intercellular space of tomato pith eight days after inoculation. The stippled cells have laid down new walls (b) in the corners of the old pith cells. The nuclei (c) occupy a position close to bacteria. Although the bacteria have been seen

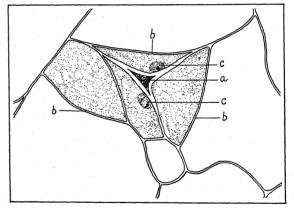

Fig. 3. Drawing made over a photomicrograph of tomato pith tissue eight days after crown gall inoculation. The bacteria (a) have reacted with the host tissue so that new walls have been formed (as at b) cutting off the stippled cells from the original pith cells. The nuclei (c) lie close to the position of the bacteria.

in the intercellular spaces and cultivated from them, this position may be of minor importance in a consideration of the physiological relation between host and parasite. The aim of our research is to determine the physiological interaction between bacteria and surrounding cells which starts pathological growth and which keeps it going.

crown gall. Amer. Jour. Cancer 25: 310-357. Abstracts of various recent contributions occur in the American Journal of Botany and Phytopathology.

This crown gall question may be approached from several directions. Just as Julius Caesar began his commentaries, "All Gaul is divided into three parts," we can divide our crown gall topic into three sections and consider in order (1) bacteriological, (2) biochemical, and (3) physiological aspects. Like many political divisions, our divisions here are rather arbitrarily made. I am particularly grateful for the opportunity to present before you this afternoon some ideas, perspectives, and results (some of which have been drawn freely from the literature) because I am confident of your help. Just as certain Romans stabbed Caesar for the good of "Democracy," I am sure you will puncture any false concepts and interpretations you detect for the good of this research program.

BACTERIOLOGY.—The pathogenicity of the crown gall bacteria in single cell culture has been examined in the hope that factors influencing its rise and fall might lead to an understanding of the means by which it stimulates cell growth. A variety of methods have been employed in an attempt to attenuate the crown gall bacteria. This was finally accomplished by carrying a culture through 10 to 20 successive transfers in a liquid medium containing glycine, a simple amino acid. Some related compounds have given similar results. While loss of pathogenicity appears in at least one case to have occurred spontaneously, it can be induced at will by this means. It also appears that the pathogenicity of glycine attenuated cultures may be gradually regained when they are restored to stock media. Frequent use of single cell cultures, at the beginning and at various intermediate points in these different steps, has satisfied us that the change is actually one in the organism itself, and quite independent of any question of mixture in the cultures. Whether one wishes to call this an induced variation, a mutation, or merely "education," is beyond the scope of this discussion. The essential fact is that pathogenicity can be increased and decreased at will by influencing the bacterial metabolism with certain of the simpler organic nitrogen compounds.

The substrata which these bacteria are able to utilize have been examined to determine what materials could be employed. Information is available concerning the utilization of all the common sources of carbon and nitrogen. We have often heard that Caesar crossed the Rubicon but kept his commentaries dry. So to avoid excessive desiccation, I shall pass over the details of these studies except to indicate that the bacteria will use most of the sources of carbon or nitrogen which they find in the plant, and many others besides. Likewise, as mentioned later, various chemical analyses of tomato stem tissue and of other host plants have shown the presence of a number of available nutrients, from some of which cell stimulating factors might be produced.

The changes the crown gall bacteria bring about in the host tissue can be roughly approached by studies with known materials in vitro.

The physical chemical changes investigated include (1) osmotic pressure, (2) hydrogen-ion concentration, (3) oxidation reduction potential, and (4) viscosity. In all but the last case, attenuated and pathogenic bacteria induce apparently similar changes. The pathogenic cultures have lower viscosity than attenuated cultures. However, this may be associated with differences in gum production and rate of growth.

BIOCHEMISTRY.—The products in the culture media, aside from the bacterial cells, depend in large part on the materials used and the conditions of incubation. From sugar, a considerable quantity of CO<sub>2</sub> and bacterial gum is produced. Studies of carbon balance show that there remains considerable unknown material, probably related to gum. When sugar was present, it had a sparing action on common organic sources of nitrogen. From peptone and its derivatives this organism, like many others, produces various materials among which ammonia and beta-indole-acetic acid have been identified. Here again attenuated and pathogenic cultures appear similar. In a synthetic medium both also produce vitamine B<sub>1</sub> in approximately the same high quantity as yeast.

In connection with the closely related hairy root bacteria it is interesting to note that some acidity is produced from sugar. The acids have been identified as acetic and pyruvic. The latter was recognized some time ago as capable of inducing root formation from certain plant tissues.

From the standpoint of the host plant, it appears that crown gall tissue is somewhat similar to embryonic plant tissue not only in certain histological characters but also in gross chemical composition. In the host there are obviously abundant sources of carbon and nitrogen in forms available to the bacteria. However, in comparison with uninfected stem tissue the gall tissue is particularly rich in oxidizing enzymes, such as catalase, oxidase, and peroxidase. The difference in tyrosinase content is still more striking. QO<sub>2</sub> measurements show, when comparisons are made on the basis of total nitrogen content, that crown gall tissue respires much more rapidly than corresponding stem tissue.

The hydrogen-ion concentration of tomato crown gall and contiguous uninfected stem tissue seems not to be significantly different, although variations in the two types of tissue have been found with other host plants. However, when a platinum electrode was inserted in gall tissue there was consistently a more positive charge than when such an electrode was placed in nearby stem tissue. This is in contrast to the fact that the bacteria lower the oxidation-reduction potential of the medium in which they grow.

PLANT PHYSIOLOGY.—Galls similar in general appearance to crown gall have been induced by various workers with a long list of different chemicals, and certain physical agencies. Some non-parasitic galls, which have similar histology as well as gross appearance, may be induced on certain plants by

successive treatments with strong (e.g., 3 per cent) beta-indole-acetic acid.

This or some other growth substance seems clearly to be associated with crown gall development as shown by (1) epinasty, (2) suppression of axillary buds, (3) secondary thickening of stems, (4) suppression of abscission layer, and (5) root stimulation. There is some evidence that the difference between the pathogenic crown gall culture and the attenuated culture may be something of this character. When the attenuated culture alone is punctured into a decapitated tomato stem there is little response of the host tissue. However, when it is below a crown gall, it produces galls practically as large as the virulent culture. With certain other conditions an attenuated culture induces adventitious shoots on tomato.

The amount of growth substance in culture or in crown gall tissue is apparently small. The largest amount found in a crown gall culture grown in peptone glucose broth was equivalent to 120 gamma beta-indole-acetic acid per liter. The amount found in certain gall tissue varied with circumstances in this general range. This is to be compared with 3 per cent (30,000,000 gamma per liter) beta-indole-acetic acid used directly to stimulate growth. The material found in host tissue seems more sensitive to acids than to bases, which suggests that it is related to beta-indole-acetic acid.

The "host ranges" of crown gall and of betaindole-acetic acid are not parallel, crown gall occurring readily on various plants where this acid is not effective in gall production. It would be surprising if various precursors and accessory factors were not involved. These and several other lines of evidence suggest that judgment should be reserved about beta-indole-acetic acid being the primary cause for the pathogenicity of crown gall bacteria.

The increase in chromosome number of crown gall cells has been reported by several workers. The chromosomes in legume root nodules are doubled. The studies just discussed by Dr. Blakeslee on increasing chromosome numbers with chemicals raise the question whether metabolites from crown gall bacteria may cause similar responses.

Some discussion seems desirable of the meaning of these various results. The crown gall literature, which borrows many of its concepts from medicine, contains a large number of working hypotheses aimed at explaining the cause of this pathological growth. These hypotheses are too numerous for discussion here. Perhaps the present most popular concept extends an older idea-viz., that the host and bacteria interact and produce a cell stimulating chemical which starts the cells on their diseased multiplication. However, it seems unwise to overlook other possibilities. For example, the physical chemical changes involved have many promising aspects. Likewise, instead of a cell stimulating material being produced, a cell regulating or inhibiting substance may be removed. The factors which start off the gall may be different from those which keep it going. From the foregoing discussion of results, I hope it is apparent that a large number of working hypotheses have been tested and found wanting. One of the greatest handicaps in this general type of work has been the lack of adequate controls on the experiments performed. Fortunately for the crown gall investigations, such checks have been developed.

Two important safeguards are worth listing. (1) In relation to the bacteria, attenuated cultures can be carried in parallel with pathogenic cultures. At least quantitative differences should be found before attributing a rôle in pathogenicity to any factor tested. (2) In relation to the tomato host, treated plants can be maintained below 28°C. where galls develop and above 30°C. where they do not. It appears that any factor responsible for pathogenicity should be much less active if not absent at the higher temperature. By means of these and similar controls research workers may avoid premature conclusions.

This work on cell stimulation with crown gall serves, I hope, as an illustration of the opportunity for attacking various basic problems in biology with plant materials.

Our colleagues, who work with animal materials, may consider that I am a "radical red" for placing so much emphasis on some of the superior advantages of using plant materials. If I should appear to be reflecting long wave lengths of light, I protest it is not because of radical tendencies, and not even of Christmas celebrations, but merely because of a glow of enthusiasm over the opportunity provided by plants for studying basic biological problems.

DEPARTMENT OF PLANT PATHOLOGY, UNIVERSITY OF WISCONSIN, MADISON, WISCONSIN

# THE PRESENT AND POTENTIAL SERVICE OF CHEMISTRY TO PLANT BREEDING 1

Albert F. Blakeslee

Your secretary, in asking me to present a paper before Section G at this meeting, suggested I report on our recent investigations with colchicine. I shall speak about colchicine but shall use this drug chiefly as an example of how chemical substances may be used in control of life processes. Like all findings, the use of colchicine to influence chromosome behavior has a history. Dustin<sup>13</sup> of Brussels first reported its action in arresting nuclear divisions. Allen introduced it to endocrinologists in this country to determine relative abundance of nuclear divisions in animal tissue. Eigsti,14 Nebel,18 and perhaps others as well as ourselves independently applied the drug to the induction of extra chromosomal types in plants. The successful use of colchicine for this purpose happened to fit into our research program.

COLCHICINE IN THE CORM OF COLCHICUM.—Colchicine occurs in the seed and corm of Colchicum autumnale (meadow saffron). The corm may contain as much as 0.4 per cent by dry weight. A concentration of 0.4 per cent in water solutions will induce doubling of chromosome number in Datura, and one-thousandth of this concentration will induce chromosome doubling and distinct swelling in seedlings of Portulaca. The Colchicum plant is not affected by the colchicine in its own cells nor is there any swelling of roots or doubling of chromosomes evident when the roots are immersed in strong concentrations of the alkaloid colchicine. It is like the snake which is immune to its own venom. We have been unsuccessful in attempts to extract an "anticolchicine" from the corm which would inhibit the action of colchicine on chromosomes of other plants. Perhaps someone will suggest how we can get out such an anticolchicine, provided the immunity of the chromosomes of this plant to its own alkaloid colchicine is not perhaps inseparably tied up in some way in the nature of the species protoplasm. We should, however, prefer to have it due to an extractable chemical compound, which we would find useful in our experiments. A few other chemicals have been found by us to have an effect similar to that exercised by colchicine, but none so far has been found which is as effective in inducing chromosome doubling. By the use of sodium cacodylate we have induced plants with doubled chromosome number in Portulaca. Acenaphthene, which Kostoff<sup>17</sup> reports having used to double chromosome numbers, seems relatively ineffective in inducing 4n plants in the species with which we have tested it.

<sup>1</sup> Received for publication January 27, 1939.

Invitation paper presented before the joint session of Section G of the A. A. A. S., the Botanical Society of America, American Phytopathological Society, American Society of Plant Physiologists, Mycological Society of America, Sullivant Moss Society, and American Fern Society, December 28, 1938.

PLANTS TREATED WITH COLCHICINE.—As is shown by table 1, in little over a year by the use of colchicine we have succeeded in doubling the chromosome number of 65 different kinds of plants if we include varieties as well as species. These are included in 41 different species, 24 genera and 14 families of flowering plants. Some in the table have been already reported by Avery and the

Table 1. List of plants with chromosomes doubled by colchicine.

# 4H SEED # = 4N OFFSPRING

speaker in a recent issue of the Journal of Heredity. The chromosomes of the others we have doubled with the help of Warmke. The list would be considerably larger if we included examples from other investigators. It is becoming apparent that the use of colchicine among the flowering plants to double the chromosome number is of rather general application, although there is considerable difference between even related species in respect to susceptibility to treatments. In addition to the species listed in the table, Miss Satina has doubled the chromosome number in Marchantia polymorpha, and we now have 2n male and female gametophytes by treating gemmae of this liverwort. Preliminary tests of some algae indicate that they also may be susceptible; at least colchicine is toxic to them and induces swollen cells. The fungi seem immune. Miss Satina has tested representatives from a wide range of families of fungi. She finds that in aqueous solutions or in agar media containing from 0.4 to 4 per cent colchicine, the fungi grow as well as in the controls. Others have told us of similar experience with fungi.

Characteristics of tetraploids.—With the accumulation of types with doubled chromosome number from an increasing number of groups, it will be possible to speak with more confidence regarding the effects which are brought about by the increase in chromosome material. We can touch upon only some of the more obvious morphological effects. The more important physiological effects must be left for further study. In discussing the appearance of tetraploids, a distinction must be

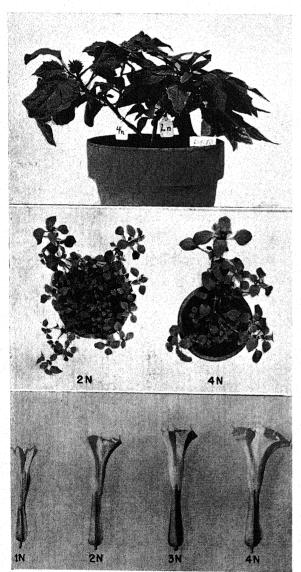

Fig. 1-3.—Fig. 1 (above). Normal 2n plant of Datura stramonium with 4n mutant branch on left.—Fig. 2 (center). Chickweed (Stellaria media). 2n plant on left, 4n on right.—Fig. 3 (below). Flowers of balanced types of Datura stramonium. From left, 1n, 2n, 3n, 4n.

made between the condition in the plant in which the tetraploidy first appears and the condition in an established 4n race. Figure 1 shows a potted plant which was photographed in 1921. The right side of the plant is normal 2n, the left side with broader roughened leaves and depressed capsule is a 4n mutant branch. The fact that spontaneous tetraploids (4n) almost invariably appeared as sectorial chimeras with roughened leaves containing mixed 2n and 4n tissue was one reason for our belief that spontaneous doubling of chromosomes in Datura at least must be brought about in somatic tissue rather than in the germ cells and must be susceptible to environmental influence. Nemec in 1904<sup>19</sup> obtained cells with doubled number of chromosomes in roots by treatment with chloral hydrate. Our earlier experiments with chloral hydrate, however, and with high and low temperatures were not successful in inducing 4n individuals. Figure 1 might serve as an illustration of a plant which had grown from a seed treated with colchicine, since it shows both the 2n and 4n branches which may develop from such treated seeds. The roughening of the leaves is also characteristic of the early effects of colchicine treatment. Ultimately smooth-leaved branches may grow out of the rough-leaved tissue. and in the next generation clean tetraploids (4n) may be expected. There is some evidence that colchicine-treated plants in the first generation may be periclinal chimeras, with the outside of the plant having a different number of chromosomes from the inside. If this turns out to be the case, we may have a method of determining definitely, for Datura at least, what layer, or layers, in the stem gives rise to egg cells and pollen grains. In view of the possibility of periclinal as well as sectorial chimeras, it has been our practice to establish tetraploid races by planting seeds from induced 4n branches before attempting critical studies on the differences between tetraploids and diploids. Tetraploids are characterized by a general greater robustness in comparison with diploids. The common chickweed (Stellaria media), in which we doubled the chromosomes unintentionally by accidental spraying with colchicine solutions, is shown in figure 2 with a normal 2n plant on left and a 4n plant on right. The leaves are characteristically broader, and stems and leaf stalks are thicker. It seems to be a general rule that leaves of tetraploids are darker green than those of diploids and a 4n sector on a 2n stem in some cases may be recognized by its darker green color. We have observed a deeper color in the flowers of tetraploid yellow cosmos which may also be due to a thicker layer of colored plastids.

As the balanced number of chromosomes increases in Datura from 1n through 2n and 3n to 4n, the flowers become progressively larger, as shown in figure 3. We have obtained 8n flowers by colchicine treatment, but such flowers have so far failed to set seed. By treating buds of 3n plants, we have obtained 6n flowers and capsules, but they have given us only very few seeds, and these have failed to

germinate. There seems to be a limit to the number of times the chromosomes of a species may be doubled and give rise to polyploid races of higher order. That increased size of flowers goes with doubled number of chromosomes seems to be a general rule. The flowers in figure 4 are typical representatives from individual offspring of a single 2n plant of Petunia, one branch of which had been treated with colchicine and induced to form 4n tis-The flowers on the left came from 12 offspring from an untreated 2n branch and are diploid. those on the right came from 12 offspring from the 4n branch and are tetraploid. Although genetic and environmental factors have an influence on the size of flowers in this species, it is obvious that doubling the number of chromosomes is of primary importance in causing the 4n flowers to average considerably larger than the 2n flowers. In certain other species such as Portulaca, however, environmental factors appear of more influence on the size of the flowers than doubling the number of chromosomes. In each pair of plants in figure 5 the

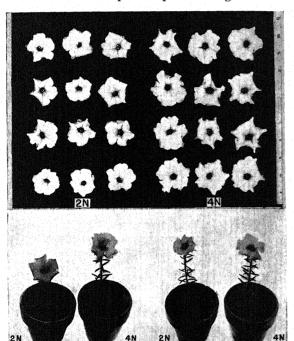

Fig. 4 (above). Flowers of garden Petunia; the 12 on left 2n, the 12 on right 4n.—Fig. 5 (below). Portulaca parana. In each pair, plant on left is 2n, that on right 4n.

plant on the left is 2n and that on the right 4n. In the right pair the flower of the 4n plant seems larger than that of the 2n, but this relation does not hold in the left pair. Neither in this species (P. parana) nor in the more common species, P. grandiflora, could one readily distinguish a 4n from a 2n plant by the size of the flowers alone. The greater thickness of the 4n leaves would be a better criterion.

In Datura the capsule tends to become progressively shorter and thicker as we go from the 1n

through the 2n and the 3n to the 4n types.<sup>4</sup> The shape in this series, however, is somewhat affected by a paucity of seeds in the uneven balanced 1n and 3n capsules. In general, doubling chromosome

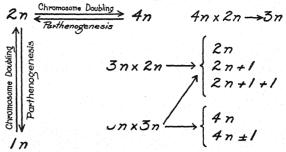

Fig. 6. Diagram showing origin from normal 2n of 1n, 4n, and 3n balanced types; and from 3n origin of 2n + 1 and 2n + 1 + 1 unbalanced types.

number makes the fruits stouter, but the effect is not uniform in all forms. An interesting series of changes in size and shape of fruit following doubling of chromosome number is shown in the Cucurbitaceae. Dr. Sinnott,<sup>23</sup> with whom we have been cooperating in a study of the effects of extra chromosomes upon morphological and anatomical structure, is attempting to relate the different types of changes in the fruits to differences in their constituent cells in respect to their number, size, and planes of division.

TETRAPLOIDS THE SOURCE OF OTHER CHROMO-SOMAL TYPES.—Doubling chromosome number not only forms a new type of plant, but, as we have shown for Datura, it also furnishes a starting point for a considerable series of new types. (The last cited paper gives a 19-year bibliography of our Datura investigations.) As shown in figure 6, we may start with a 4n individual and by crossing it

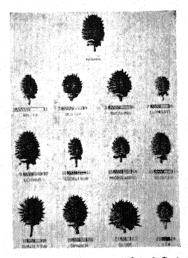

Fig. 7. Top, a normal 2n capsule of  $Datura\ stramonium$ ; below, capsules of the 12 primary 2n+1 types arranged from upper left to lower right in order of decreasing size of the chromosome which is extra.

with a normal 2n get a 3n plant. The 3n may then be selfed or, better, crossed with a 2n to give the full range of primary simple trisomic (2n+1) types each with a different extra chromosome (fig. 7). In addition, double trisomic (2n+1+1) types are to be expected in relatively large numbers. Such trisomic types have been of value in analyzing the content of genes in the individual chromosomes by the changes brought about when they are present as extras and have been used in  $Datura^{11}$  and maize<sup>20</sup> in locating genes by trisomic ratios.

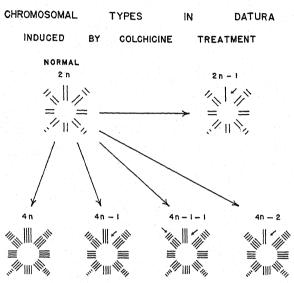

Fig. 8. Chromosomal types in Datura induced by colchicine treatment.

CHROMOSOMAL DEFICIENCIES FROM COLCHICINE TREATMENT.—We have spoken as if doubling chromosome number were the only change induced by colchicine. That this is not the case we were early led to conclude from the appearance of plants grown from treated seeds. This last summer we had growing in the field more than two thousand Datura plants from seeds which had been treated with 0.2 and 0.4 per cent solutions of colchicine for different lengths of time from 3 to 8 days. From all these treatments, plants with abnormal sectors were abundant. They amounted to from 55 to 77 per cent from the 0.4 per cent treatments. While most of the abnormal sectors could be classified as  $\pm 4n$  by appearance, many were obviously modified 2n or 4n branches. With the help of Avery we selected a couple of hundred for cytological study by Dr. Bergner. Figure 8 shows some of the simpler chromosomal types that were identified from study of pollen mother cells. Of the 2n-1type at the right, we have identified 7 cases. One of these had lost the largest (1.2) chromosome as indicated in the diagram. We have already spoken of the value of the 12 primary 2n+1 types in Datura. Capsules of these are shown in figure 7. By the use of colchicine we now have a method of getting 2n-1 types and should be able to learn more

about the factors in individual chromosomes by comparing the effects brought about by the loss of a given chromosome with those brought about by the presence of the same chromosome as an extra. It may be difficult to secure the full twelve 2n-1 types, however, and when found, they will have to kept going by grafts and cuttings, since they cannot be propagated by seed, because deficiencies are not viable in the gametophyte. On the lower line of the diagram are shown 4n and modified 4n types. Of these the simplest was brought about by the loss of a single chromosome after doubling had taken place to give 4n-1 types. There were 16 4n-1 branches identified. Of those which had lost two chromosomes there were two types. In the first, a single chromosome had been eliminated from each of two sets to form 4n-1-1types. In the second, two chromosomes were lacking from a single set. Such 4n-2 types could have arisen from doubling the chromosomes of a 2n-1 type after the elimination of its deficient chromo-

There were 10 of the 4n-2 types to 2 of the 4n-1-1 types. The 4n-2 types may be expected to form 2n-1 gametes and to breed true for the deficiency. They should give disomic inheritance for genes in the set with the deficiency and tetrasomic inheritance<sup>9</sup> in other sets. If their reduced eggs could be induced to develop parthenogenetically, we should have a further source of 2n-1 plants. Another source would be the 4n-1 types, half of the eggs of which should be 2n-1. Various combinations of the modified 4n types given in the table have been identified. The most complicated had 42 chromosomes with a chromosomal constitution represented by the formula 4n-1-1-1-2.

Doubling chromosomes in haploids.—We have spoken of doubling chromosome numbers of diploids. They may be readily doubled also in haploids. Haploids of some species never produce seeds, and in some races of *Datura stramonium* our efforts to secure seeds have been fruitless. In our main line an occasional capsule on older haploids

Fig. 9. A haploid (1n) plant of D. stramonium which has been sprayed with colchicine. Note the 2 large 2n capsules toward right and left of picture which had been induced by the treatment. A small typical 1n capsule is seen at upper center.

will be found to have formed one or two seeds by non-reduction, but the large majority of haploid flowers are sterile. In figure 9 we have a photograph of a haploid plant which has been sprayed with a 0.4 per cent solution of colchicine. The two large diploid capsules which have been induced by the treatment are in contrast to the typically small 1n capsule at the upper middle of the picture. The capsule of intermediate size half way to the left is perhaps a mixture of 1n and 2n tissue.

Now that we have learned how to induce haploids to double their chromosome number and become diploids, how can we use this knowledge in a plantbreeding program? We could make great use of it if we could only induce the production of haploids. As shown by figure 10, we could start with a highly heterozygous plant such as a fertile species hybrid and by parthenogenesis of a reduced egg obtain a haploid with only one of each kind of chromosome. Each of these haploid chromosomes could be doubled by treatment with colchicine to give homozygous seeds with each kind of chromosome duplicated. All we need to get pure lines from heterozygous material by two jumps is a method of inducing parthenogenesis. Since we first identified a haploid in 1921 we have recorded the spontaneous appearance of 216 haploids in Datura, 22 but we do not yet know the factors responsible for their occurrence.

# 2n HETEROZYGOUS

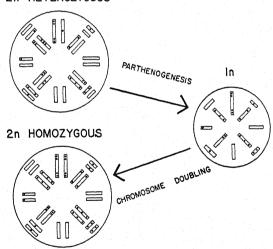

Fig. 10. Diagram showing method of securing pure lines from heterozygous material.

Last winter Warmke found that by treating unpollinated pistils with indol-butyric acid, he could induce them to develop into small capsules, which, however, never formed seeds. Buchholz had earlier noticed that he could induce formation of seedless capsules by applications of pollen which had been treated with heavy dosages of X-rays. This last summer Warmke and Buchholz combined the two methods but without success in inducing parthenogenetic seeds. Other stimuli are being tested with both 2n and with 4n parents. Success seems more

likely with the latter, since 2n in addition to 3n offspring are occasionally induced by the cross  $4n \times 2n$ . We should be glad of any suggestions how to induce parthenogenesis since this is one of the things we are eagerly yearning to do.

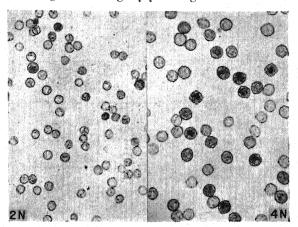

Fig. 11. Pollen of hemp, from 2n flowers on left, from 4n flowers on right. Note larger grains in latter.

Polyploidy and sex.—Among the problems connected with polyploidy is the effect of doubling chromosome number upon the sex of dioecious plants, which is being studied with Warmke. Hagerup's discovery in the arctic regions of a tetraploid hermophroditic species, Empetrum hermaphroditum, 16 which is closely related to the diploid dioecious species E. nigrum gave presumption for the belief that doubling chromosome number would change a dioecious into an hermaphroditic species. Experiments with hemp and Lychnis show that tetraploids, at least of these species, remain dioecious. Among tetraploids of spinach we have gotten male, female, and hermaphroditic plants.

Some of the difficulties of working with dioecious forms may be illustrated by our experience with hemp. Although organs of a 4n branch are more robust than those of a 2n branch, more reliable criteria than general appearance are needed, espe-

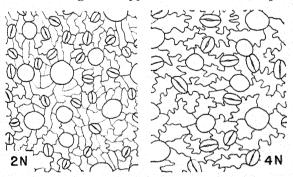

Fig. 12. Drawings from surface of 2n (left) and 4n (right) leaves of female hemp. Note larger size of epidermal and especially guard cells in 4n leaves. Circles represent cross sections of glandular hairs which are not greatly affected in size by chromosome number.

cially for the treated generation. The larger size of pollen grains from a 4n flower, shown in figure 11, is a good criterion for male plants but cannot be applied to females. The larger size of

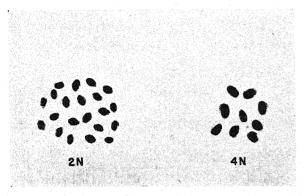

Fig. 13. Seeds from 2n (left) and 4n (right) flowers of hemp. Note larger size of latter.

stomata, shown in figure 12, is characteristic of tetraploids but holds strictly only for comparable leaves. In the figure it will be noted that the epidermal cells as well as the guard cells are larger in the 4n leaf but that there is no material difference in the size of cross sections of the glandular hairs which are shown by circles in the drawing. Stomatal size was found a reliable criterion when the stomata were taken from the floral bracts of females. In figure 13 are shown 2n and 4n seeds

of hemp. In all species so far examined, the 4n are distinctly larger than the 2n seeds.

MULTIPLE DIPLOIDS.—We are most of us familiar with sterile hybrids between plant species. They are like the sturdy mule in that they cannot form gametes since the chromosomes of one parent are too unlike those of the other parent to mate and form pairs; and pairing of chromosomes is necessary for sexual reproduction. Very rarely such sterile hybrids have been rendered fertile by spontaneous chromosome doubling. Now, however, we are able to induce such doubling at will by chemical How this is brought about may be treatment. clearer from the diagrams of figure 14. The chromosomes of species A are represented by solid lines, those of species B by dotted lines. Each species is assumed to have 4 different sets or kinds of chromosomes. In the sporophyte there are 2 chromosomes in each set, but in the gametophyte and gametes the number is reduced to half, and each set contains only one chromosome. In the hybrid between species A and B the chromosomes are assumed to be unable to pair, with resultant sterility of pollen and egg cells. In the sterile hybrid there is only one chromosome in each set but there are now 8 sets or as many sets as in both the two parents combined. Such a sterile hybrid, therefore, is a double haploid. By the use of colchicine the chromosomes may be doubled. The resulting type will be diploid, since it has two chromosomes in each of the 8 sets. It will be fertile, since each of the chromosomes of both species A and B will have duplicates from their own species with which to

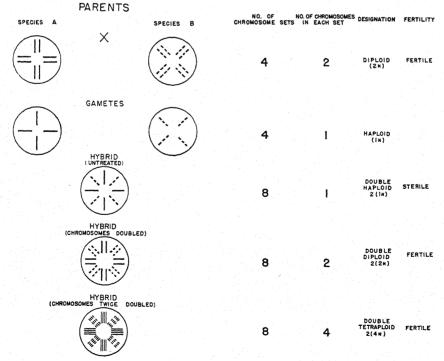

Fig. 14. Diagram to show method of induction of double diploids and double tetraploids from double haploids through doubling chromosome number.

pair. Since the number of sets is the sum of those from two parents, it may be called a double diploid. If the number of chromosomes were again doubled there would be 4 chromosomes in each set, and the plant should be called a double tetraploid.

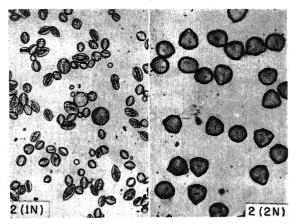

Fig. 15. Pollen from the hybrid *Nicotiana glutinosa*  $\times$  *N. sylvestris*. On left aborted grains from sterile double haploid flowers, on right good grains from fertile double diploid flowers.

The word tetraploid means 4-fold and would seem applicable only to cases in which each kind of chromosome is represented 4 times. The term amphidiploid as a Latin equivalent of our double diploid describes what actually happened to the chromosomes. Allotetraploid is an unfortunate term since it emphasizes the mere change in total number without regard to how this change has been brought

about. In a terminology regarding changes in chromosome number we believe it will give a clearer picture of what happens if we focus our attention upon the different kinds or sets of chromosomes the members of which are doubled, tripled, or quadrupled to form 2n, 3n, or 4n types. We suggest the terms simple and multiple polyploid instead of autoand allo-polyploid.

We have gotten the second generation of a double diploid race through the use of colchicine in doubling the chromosome number of a sterile hybrid between Nicotiana glutinosa and N. sylvestris,24 cuttings of which had been kindly sent us by Dr. F. O. Holmes. Sterile hybrids between these two species have been known for some time, but so far as we are aware, the fertile double diploid has not been reported before. From figure 15 it will be seen that the aborted pollen of the sterile hybrid can be readily distinguished from the good pollen of the induced fertile hybrid. In addition to the condition of the pollen, the setting of the capsules is good evidence that a double haploid has been transformed into a double diploid and become a fertile hybrid. Judging from the roughened leaves of a treated double diploid seedling secured from the cross N. tabacum  $\times$  N. glutinosa, 12 we are on the way to produce the double tetraploid shown in diagram in the lower part of figure 14.

In figure 16 is shown by diagrams the methods by which it might be possible to build up triple and quadruple diploids. If  $Nicotiana\ tabacum$  is already a double diploid, as specialists in this genus believe, 15 we have recently built up a triple diploid race from the sterile hybrid  $N.\ tabacum \times N.\ glutinosa$ . Cooperative studies on the genus Nico-

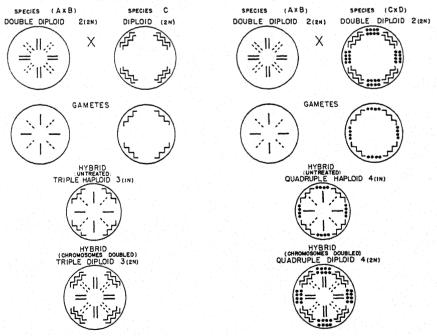

Fig. 16. Diagram to show method of induction of multiple diploids through doubling chromosome number.

tiana which are being undertaken with Dr. Holmes may give us before another Christmas meeting quadruple and even quintuple diploid races. A limitation to the formation of such multiple diploids is the number of hybrid combinations which are sterile because of chromosome incompatibility. In Datura, for example, multiple diploids have not been formed, since none of the hybrid combinations within the 10 herbaceous species are sterile from lack of chromosome compatibility. It seems unlikely that chemical methods could be found that would permanently prevent compatibility between chromosomes in these fertile hybrids, since this would appear to involve simultaneous mass mutations in all the chromosomes. It is more likely that genes might be found that would decrease compatibility between chromosomes belonging to different species but permit pairing of chromosomes belonging to the same species. This is suggested, since there are already known genes in Datura and maize which prevent pairing of chromosomes altogether within these species.

Multiple diploids are of interest to the student of evolution, since the evidence is strong that they represent a method of evolution of species in nature. We now have an opportunity to make new species to order.

Multiple diploids should have hybrid vigor like the mule, and the desirable characteristics brought about by doubling chromosome number. The possibilities in the way of new forms of economic value seem very great. In a number of cases sterile hybrids between species have been made fertile through spontaneous doubling of chromosome number which had taken place before recorded history. These fertile hybrid races were preserved by prehistoric man because of their superior qualities. Among such fertile races which have developed from species hybrids through doubling chromosome number may be mentioned our best varieties of wheat, oats, timothy, tobacco, and cotton. We now no longer have to wait ages for the chance hybridization between species and the later rare spontaneous doubling of their chromosomes in order to secure such superior varieties. We can now make them up to order.

We have told something about the recent work with colchicine as an example of how a chemical method can be of service to one branch of botanical science. In the few minutes remaining we shall suggest some other ways in which botany might be aided by chemistry.

IDENTIFICATION OF GENETIC TYPES BY CHEMICAL REAGENTS.—Many years ago we found a single plant of a yellow-coned variety of the Black Eyed Susan (Rudbeckia hirta) near the grounds of the Connecticut State College, and several similar yellow-coned plants some 7 or 8 miles away. Since Rudbeckia is self sterile, we crossed together the yellow-coned plant from the first locality with one from the second locality. To our surprise we got normal purple-coned offspring. The purple cones

in the F<sub>1</sub> and the type of segregation in later generations proved that we were dealing with two kinds of yellow cones, although we could not distinguish them apart by appearance. It occurred to us, however, that they must differ chemically and that it might be possible to tell them apart by use of some chemical reagents. We therefore tested the two kinds of yellow cones with all the substances we could find in the chemical laboratory. Since we knew no reason for selecting one reagent rather than another, we tried them out in the order in which the bottles stood on the shelves. We were rewarded by finding that strong KOH and NaOH (but not NH4OH) would turn the yellow cones of one race black and these we called the Black Yellow race, while the same reagents would turn the yellow cones of the other race red and these we called the Red Yellows. It was an easy task then for an assistant with a bottle of KOH to separate a segregating group of yellow-coned plants into the two genetic types, Black Yellows and Red Yellows.2 By a chemical method he could discover in one afternoon the genetic constitution of more yellow-coned plants than we could discover in a whole summer spent in making crosses to tester types and a second season in planting and recording the back-cross progenies. We believe that chemical methods of distinguishing other genetic types that look alike will ultimately be worked out. Especially useful to the breeder would be chemical methods of distinguishing homozygous individuals from those heterozygous for a given trait. Such methods would be most valuable with the slower breeding organ-The difficulty of distinguishing carriers of deleterious recessive traits from individuals free from them is the reason why geneticists doubt the possibility of eradicating or even greatly reducing the number of feeble-minded individuals, for example, in the human population by preventing the breeding of the homozygous recessives which alone can be recognized. A chemical method of recognizing the heterozygous carriers, if utilized, should enable the recessive trait to be eliminated from the population in a single generation. The reference to humans may indicate the tremendous importance which such chemical methods might have, but, as in many other biological problems affecting human beings, we shall probably have to look to botanists to lead the way.

OTHER CHEMICAL SERVICE NEEDED.—I shall merely mention some of the other ways in which I hope chemistry will be of service to plant breeding.

I want to have a method of inducing shoots to grow from any part of the plant—stem, root, or leaf. That this may be possible is suggested by the fact that certain species have this power to produce shoots to a marked degree. In Datura, moreover, the 17-18 chromosome when present as an extra induces abundant formation of adventitious leaves and shoots in continuous lines along the stem. The factors in this stimulus we have located in the 18

half chromosome. I had down in my notes to say that since Robbins and White had worked out the methods of growing excised roots in artificial media, we ought to be able to devise methods of growing tissue cultures of plants and be in a position to regenerate a whole plant from any single cell. I notice from the abstracts of this meeting that White has already started growing tissue cultures of callus cells.

We very much need chemical stimuli that will induce crossability or remove the block to crossability between species which we are attempting to investigate genetically.

We need also methods to induce a continuation of growth after fertilization in certain wide crosses. Considerable progress has been made by different investigators in getting arrested embryos to develop through to seedlings, but we are still looking for a method of coaxing the proembryo from the cross  $Datura\ stramonium\ imes\ D.\ metel$  to develop any further than an 8 cell stage. 21

We do not know what the chemical differences are in the environment within the ovules and anthers which bring about the reduction divisions of chromosomes. If we did know, we might be able to get reduction divisions in roots or in any other part that was most convenient.

We have frequently asked the *Drosophila* workers what makes the chromosomes behave the way they do in the salivary glands of their domesticated diptera so that they are 150 to 200 times their size in other parts of these insects. They can't tell us. If they could, we might be able to borrow some of

the chemicals which *Drosophila* uses and get giant chromosomes in some useful plant like the Jimson weed.

I am still enough of a mycologist to want to see some method developed of growing fungous parasites such as the rusts on artificial media. By rather simple adjustment to the nutritional requirements, Miss Satina and I have been able to grow the parasites Chaetocladium and Parasitella without the presence of the usual mucor hosts. With increasing knowledge of growth substances it ought not to be long before rusts are grown on agar in test tubes.

LEARNING BY YEARNING.—I have mentioned only some of the things I yearn to be able to do. Perhaps these may be considered botanical luxuries. It must not be forgotten, however, that civilization has advanced more by yearning for luxuries than by struggling for existence. What we need is to get more people yearning for things they don't know they want. So far as the probable results are concerned, I believe it would be more profitable to cut down on the lengths of papers at science meetings and to devote the time thus saved to periods of yearning-yearning by each for the luxuries that seem unattainable in his own scientific hobby. I find I have saved one minute and a half of the time allotted me and this I am donating to the section toward such a period of yearning.

# THE RELATION BETWEEN STRUCTURE AND FUNCTION OF THE PHLOEM <sup>1</sup>

## A. S. Crafts

NEARLY THREE HUNDRED years have passed since Malpighi ringed plants to study conduction, and more than two hundred since Hales' memorable experiments on sap movement. Eighty years ago Theodor Hartig (1858) postulated that the principal movement of organic solutes occurs in the phloem. Only within the last decade, after years of devious experimentation, have plant physiologists returned to this view. Ringing experiments, chemical analyses of tissues and exudates, and studies with dyes, viruses, and radioactive elements support the view that rapid longitudinal transport occurs in the sieve tubes.

On the mechanism of movement in the sieve tubes, however, there is still controversy. As recently proposed (Crafts, 1938), workers in this field may be grouped as follows: (1) those who attribute rapid diffusional movement of solute molecules to a specialized activity of the sieve tube protoplasm and (2) those who picture a flow of solution through perforate or permeable elements resulting from a gradient of hydrostatic pressure developed osmotically. Views of the first have been termed the "protoplasmic" theories; those of the second, the "pressure flow" theories (Crafts, 1938). Huber (1937) has classified them as the "diffusion" and the "convection" theories.

Recent calculations indicate that acceleration of solute movement via the protoplasm must be several million times the normal rate of diffusion when it is based upon the actual space available within the protoplasm (Crafts, 1938). Advocates of the protoplasmic theories assume that this acceleration is accomplished by rapid streaming, activated diffusion, or the application of surface forces within the sieve tubes. Postulating the independent movement of different molecules, these theories demand the utilization of high energies (Mason and

<sup>1</sup> Received for publication January 24, 1939.

He also wishes to express his appreciation to Professor I. W. Bailey for many helpful suggestions during the course of the studies.

Phillis, 1937) to overcome the internal resistances of the system. In the pressure flow mechanism, solvent and solute are assumed to flow together as a solution through elements of specialized structure or permeability, the protoplasm of which plays an entirely passive rôle in the process. The sources of energy in this mechanism lie in the osmotic activity of the products of assimilation in green portions of the plant and in the accumulative ability of cells in growing and storing tissues.

With such widely differing views on the rôle of the sieve tube protoplasm in conduction, studies on the structure and vital activities of sieve tube elements should provide useful data for the solution of this problem.

PLASMODESMATA.—The classical concept of the sieve tube as a series of elements with end walls perforated to facilitate rapid longitudinal movement was developed largely from the works of Hartig (1854, 1858), Nägeli (1861), Strasburger (1891), and Hill (1908) and resulted from an attempt to reconcile microscopic impressions of sectioned tissues of lianas and woody angiosperms with the commonly observed phloem exudation. Though the earlier workers pictured the sieve plate plasmodesmata as tubular in nature, Strasburger (1891) questioned this in the gymnosperms. Hill (1908) felt compelled to accept their tubular structure, though he did not picture it in his own illustrations. Schmidt (1917) cast serious doubt on the tubular nature of sieve plate connections, and, with our present progress in microscopic equipment, staining technics, and understanding of protoplasmic properties, it seems certain that these structures are solid. According to present views, the mature functioning sieve tube is a series of elongated cells devoid of nuclei, each lined by a thin parietal layer of protoplasm surrounding a large central vacuole, containing an aqueous solution, within which may be suspended starch grains in varying numbers. Sieve tube elements are connected with neighboring cells by plasmodesmata, and, because of the great affinity of the protoplasm for dyes during certain stages of ontogeny, the connections between adjacent sieve tube elements may be particularly prominent.

Figure 1 shows the plasmodesmata of the sieve plate of squash, and figure 2 illustrates the response of one of these massive, solid connections to cutting the stem. The intense and sudden steepening of the pressure gradient by cutting in the region shown at the lower side of the figure caused one plasmodesma to be forced from its position and inflated within the lower cell. Filled with the slimy sap resulting from disintegration of the nucleus and slime drops, it stains intensely, illustrating by its bladder-like form the fact that the strand from which it was produced was not tubular. These structures have been pictured by Nägeli (1861) and others and occur commonly in cucurbits, ash, and other rapidly exuding plants. Figure 3 shows the long, thin plasmodesmata of the calloused sieve plate of Catalpa and indicates their slender structure and the great elasticity of the protoplasm of which they are composed. Modern microscopic methods, particularly when used upon gymnosperms and many of the lower plants, show definitely that the plasmodesmata between sieve tube elements are not tubular. The thesis that sieve plates are perforate, and thus facilitate mass flow of solution, can no longer be defended.

PHLOEM EXUDATION.—Work by Hartig (1858), Nägeli (1861), Münch (1930), Crafts (1931, 1932, 1936), and Huber, Schmidt, and Jahnel (1937) makes it increasingly evident that mass flow of a sugary solution does occur through sieve tubes, at least in cut stems. These experiments show that phloem exudation occurs in many species, that it takes place at rates well above those normally required to account for growth and storage (Crafts, 1931), and that it may be maintained indefinitely if the phloem is kept open (Crafts, 1936). Linear rates of displacement equivalent to 15 cm. per minute through the sieve tubes have been recorded in cucumber. Exudation was continued for 24 hours in squash by frequent cutting of the stem; and in Macrocystis, which has well developed phloem, plugging is much slower, so that exudation will continue for an hour or more without cutting and can be reestablished by simply cleaning away the mucilage which coagulates on the end of a cut or broken stipe. There can be no question as to the origin of this exudate, since there is no xylem in Macrocystis, and the sieve tubes of the phloem are the only specialized elements capable of such rapid conduction. Three other species of kelps also exuded copiously from the phloem.

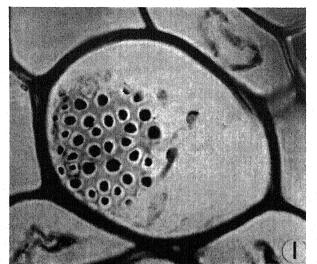

Calculations on the rate of sap displacement in exudation experiments show the values presented in table 1. It is evident from these figures that. since the length of sieve tubes having their contents displaced exceeded the stem length (Crafts. 1936), elements other than those actually cut are involved; in fact, the only logical interpretation seems to be that the exuded solution is moving from considerable distances along permeable elements. Slime plugs (fig. 4) may be found in the sieve tube elements of cucurbits for a distance of several centimeters back from the cut end if the stem is killed in hot water or alcohol. If 1 cm. portions are cut from the stem and killed in alcohol, these structures may be found on the distal sides of the sieve plates at both ends of the section, and in some place between the ends the situation pictured in figure 5 may be found. Here the slime accumulations in adjacent cells are pointed in opposite directions. the plasmodesmata of the sieve plate were tubular, the slime plugs of figure 4 would not occur. It would likewise be difficult to account for their formation if there were no flow of solution through the cytoplasm covering the end wall.

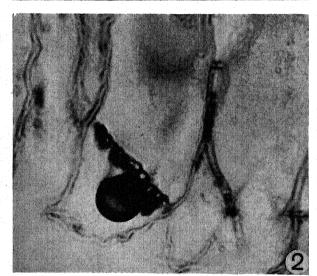

If phloem exudation is causally related to phloem conduction and dependent upon a permeable state of the sieve tube protoplasm, it should be demonstrable in all actively assimilating plants. A simple test has shown that it is. When the rapidly assimilating shoot of any plant is excised and the diagonally-cut end immediately placed in a tube of water, careful observation will show a narrow column of dense liquid descending from the phloem region. Observation of the descending stream depends upon the difference in refraction caused by the density gradient at its boundaries. This test has been conducted on more than 60 species, to date, and has never failed when active shoots were

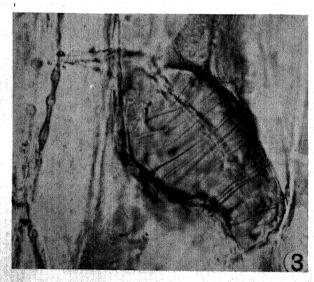

Refinement of the technic of Münch has further shown that phloem exudation can be demonstrated quantitatively in most woody species. Active phloem exudation has been confirmed in white pine and other conifers where plasmodesmata in the sieve areas are notably slender. Huber, Schmidt, and Jahnel (1937) have recently given an excellent picture of concentration gradients correlated

Table 1. Sap displacement rates in pumpkin, cucumber, squash, and kelp.

	Displacement based on		Duration Tissue removed of the by repeated		
Plant used	Phloem	Sieve tubes	experiment		Citation
Pumpkin	13.7 cm.	68.5 cm.	21 min.	1.0 cm.	Crafts (1931)

overemphasized.

with the height of sampling in a number of trees.

MECHANISM OF SOLUTE MOVEMENT.—We are now faced with the problem of explaining a demonstrated exudation through elements having no intervacuolar pores. The following solution, related to the physical properties of sieve tube protoplasm and intimately connected with phloem ontogeny, is

proposed.

A reconnaissance of phloem ontogeny in many species emphasizes the fact that the young sieve tube element, rapidly expanding under a high turgor pressure, is a nucleate cell with active streaming protoplasm surrounding vacuoles of high osmotic concentration. These cells have the ability to accumulate vital stains and plasmolyse normally in hypertonic solutions. At maturity the nucleus of the element expands, becomes diffuse, disintegrates, and is lost as a discrete entity. This fact cannot be

Accompanying nuclear disintegration, the cytoplasm ceases streaming, loses its clear distinct inner phase boundary, becomes thin, fibroid, elastic, and heavily staining, and fails to plasmolyse in hypertonic solutions. Having lost its ability to retain solutes within its vacuoles, it assumes a truly parietal position and becomes permeable to solutes as are the walls. In this condition it persists throughout the period in which the sieve tubes function in rapid longitudinal conduction. At death the protoplasm and definitive callus are dissolved, and air enters the flattened or crushed elements.

In 1931 the above facts were reported, backed by only a few isolated observations. Within the past six months, however, a survey covering some 58 species of widely diverse character has shown that the most constant features of the mature sieve tube cell are: (1) it is enucleate; (2) it does not accumulate vital stains; (3) it fails to plasmolyse; and (4) being almost devoid of stainable contents, it is clear and translucent in appearance. These features clearly indicate that the mature sieve tube element becomes highly permeable, an interpretation that has recently been confirmed by Huber and Rouschal (1938).

Table 2 lists the genera, one or more species of which have been tested for sieve tube permeability. In these tests longitudinal tangential sections of living stems were cut through the phloem and cambium. These sections, usually 40 to 80  $\mu$  in thickness, were placed in dilute neutral red in M/80

borate buffer solution at pH 7.8 (Bailey and Zirkle, 1931). After allowing time for accumulation of the vital stain, the sections were mounted and studied under the microscope. Having selected a favorable location on the section, including, wherever possible, both young and mature sieve tubes in an uninjured condition, the mounting solution was replaced by hypertonic sucrose solution. This was accomplished under observation by adding the sucrose solution on one side of the cover glass and withdrawing the mounting solution from the other side by means of filter paper. The clear, translucent appearance of mature sieve tubes, their paucity of stainable contents, and their failure to plasmolyse constituted their most characteristic properties.

These common features of sieve elements, constant throughout many plants, apparently characterize phloem conductors in all plants and are of diagnostic value in identification of vascular tissues in fossil remains. They should aid materially in building a clearer concept of the origin and extent of vascularization of plants. Added to the evidence on protoplasmic connections and phloem exudation, these facts seem to favor the mass flow interpretation of phloem conduction.

Discussion.—Much of the argument for the protoplasmic theories rests upon alleged evidences for independent movement of solutes in the phloem.

Fig. 1-5.—Fig. 1. Transverse section of squash, showing a portion of a sieve plate with dense, solid protoplasmic connections, light-colored callus cylinders through a gray cellulose matrix. ×700.—Fig. 2. Longitudinal section of squash, showing a bladder-like structure formed by the pressing through and inflation of one of the connections of the sieve plate. Found near the cut end of a rapidly growing young stem. ×700.—Fig. 3. Heavily calloused sieve plate of Catalpa, as shown in longitudinal tangential section. Protoplasmic connections are stretched to many times their original length. ×700.—Fig. 4. Slime plugs near cut end of young, rapidly growing squash stem. These structures consist of colloidal products of the disintegration of the slime drops and nucleus filtered from the flowing sap by the parietal cytoplasmic layer of the sieve tube element. ×350.—Fig. 5. Slime plugs as in figure 4 may be found on the distal sides of sieve plates at both ends of a one-centimeter section of squash stem. Near the center of the stem the contents are less densely accumulated, and in one region of each phloem strand the condition shown here is found. This figure shows the region from which sap flowed in opposite directions to the two ends of the stem section. ×250.—Figures 1, 2, 4, and 5 from a slide by Dr. Esau.

Yet, according to a recent analysis (Crafts, 1938), despite many attempts (Phillis and Mason, 1936; Palmquist, 1938), there has not been described a single critical experiment proving rapid independent movement in the sieve tubes. In the meantime, C. W. Bennett (1934, 1935, 1936, 1937) has built a consistent picture of the conduction of curly-top virus in the sugar beet that can be explained only on the basis of a correlated movement of virus and assimilates by mass flow. With no adequate demonstration of independent movement of solutes at rates of 20 cm. per hour or more through the phloem, experiments on translocation can be explained more logically on the basis of mass flow.

Insufficient attention has been given the fact that the functioning sieve tube element is devoid of a nucleus. The profound changes in the cytoplasm that result from this condition have been largely overlooked (Schumacher, 1933; Mason and Phillis, 1937). The whole history of the sieve tube portrays the intimate relation of the nucleus to the structure and function of the elements. No student of ontogeny can fail to sense the influence that the loss of nucleus has upon subsequent activity. From the beginning of its functioning period to its death, the sieve tube element is doomed to a passive rôle, conditioned by its lack of nucleus and consequent permeability. The only remaining evidences of life are the maintenance within the vacuole of a fluid state, the continued development of callus to its ultimate definitive condition, and a peculiar responsiveness to stains (Schumacher, 1930).

Until the proponents of the protoplasmic theories can produce some concrete evidence for protoplasmic streaming or a high activity state in the protoplasm of the mature sieve tube, there is no bridge for the obvious gap between their experimental data and their final interpretation. Studies on sieve tube ontogeny, on phloem exudation, and on virus movement all point to a mass flow mechanism.

### SUMMARY

Careful studies using modern microscopic equipment and improved technics show that the plasmodesmata of sieve plates are solid and not tubular in structure.

Experiments indicate that phloem exudation occurs in many plants, that it takes place at rates above those required to account for growth and storage, and that it may be maintained indefinitely. Slime plugs of particulate or colloidal material are formed by the filtering out of sieve tube contents by protoplasm on the sieve plates. They indicate a mass flow of sap through the lumina.

A simple technic using the difference in density between phloem exudate and water has revealed phloem exudation in all species tested. Refinement of the Münch technic has given a quantitative demonstration of phloem exudation in many woody species, including white pine.

A reconnaissance of phloem ontogeny in many species emphasizes that, whereas the young sieve tube is a nucleate cell with active streaming protoplasm surrounding vacuoles of high osmotic concentration, the mature element is enucleate and fails to plasmolyse in hypertonic solutions. It is assumed that this indicates a high state of permeability in mature sieve tubes.

Tests on 58 species, ranging from the mosses and giant kelps to the most highly specialized angiosperms, show that this permeable state of the mature sieve tubes may characterize these elements in all plants. The common occurrence of phloem exudation and permeable sieve tubes supports the pressure-flow mechanism of the translocation of organic solutes in plants.

### A DEVELOPMENTAL ANALYSIS OF THE RELATION BETWEEN CELL SIZE AND FRUIT SIZE IN CUCURBITS!

Edmund W. Sinnott

THE PROBLEM of the relation between cell size and organ or body size in plants has been extensively studied and forms the basis of a considerable literature, but the lack of any general agreement in the results obtained indicates that the question is not a simple one. Sachs (1893) and Amelung (1893) presented evidence that size differences in body and organ are due primarily to differences in the number rather than in the size of their constituent cells, and this conclusion has been frequently confirmed. Other workers, however, among them the present writer (1930), have found that in many cases differences in organ size are in part, at least, related to cell size. Almost all the evidence has been gathered from a study of organs and cells which had reached maturity. Both structures attain final size, however, as the result of growth from small beginnings; and a developmental analysis of the growing organ in terms of changes in the size and in the number of its cells should yield important results. A study of the whole developmental process, with particular reference to the relative rates and durations of cell division and cell expansion, is evidently needed as a fundamental approach to the problem. Such studies have been made in only a few cases. Notable among these is the work of Houghtaling (1935) on tomatoes, in which she showed that early fruit growth is due chiefly to cell multiplication and later growth entirely to cell expansion and that the extent of both these processes was greater in the larger fruits than in the smaller ones. Similar results have been reported by MacArthur and Butler (1938).

The present study was undertaken to determine the developmental relations between cell size, cell number, and ovary and fruit size in several genera of the Cucurbitaceae and particularly in various races of Cucurbita Pepo differing markedly in fruit size.

The writer wishes to express his sincere thanks to Mrs. Helen Houghtaling Kaltenborn, Mrs. Mary Roscoe Vestal, and Miss Elizabeth Lane Toole, who have been associated with him at various times in the study of this problem, for their skilful assistance in the gathering and analysis of data and for many helpful suggestions. For financial support of this investigation he is greatly indebted to the Fund for Research of Columbia University.

MATERIALS AND METHODS.—Ovaries and fruits of the genera Cucurbita, Lagenaria, Cucumis and Citrullus were studied. Cucurbita Pepo provides particularly favorable material because of the great variation in fruit size between races of this species. The forms studied were members of inbred and es-

<sup>1</sup> Received for publication February 8, 1939.

sentially pure races. The twelve races analyzed are as follows: in Cucurbita Pepo, Race CF, from the "Connecticut Field" type of pumpkin, about 300 mm. in diameter; Race MT, from the "Mammoth Tours" type of pumpkin, about 360 mm. in diameter; Race M35, from the "King of the Mammoths" type of pumpkin, more than 300 mm. in diameter; Race 103, a segregated, nearly spherical race about 120 mm. in diameter; Race SRC, a Chinese gourd, about 60 mm. in diameter; Race SP, from a "spoon" type of gourd, about 45 mm. in diameter; and Race TA, a small, pear-shaped gourd about 40 mm. in diameter. In Lagenaria vulgaris, Race GB is from a large "Bottle" type of gourd, about 170 mm. in diameter; Race CN is from the "Crane's Neck" type of gourd, more than 100 mm, in diameter, and Race CL from the "Club" type of gourd, about 100 mm. in diameter. In addition to these there were studied Race G, from the West Indian gherkin, Cucumis Anguria, about 30 mm. in diameter; and Race WM, a variety of watermelon, Citrullus vulgaris, about 300 mm. in diameter. In Cucurbita the largest type thus has fruits more than 700 times the volume of the smallest, and the large pumpkin is considerably more than 1,000 times the volume of the gherkin.

The plants were grown in the field, at the same place, and under as nearly uniform conditions of soil and culture as possible. Material was collected at many stages from very small ovaries to mature fruit. The smallest were from 1-2 mm, wide, the size at which the ovary becomes organized as such and can readily be measured. The two major dimensions were measured; width at the widest point and length from the point where stalk and ovary join to the constriction between ovary and calyx lobes. With small ovaries the entire organ was collected, but in larger ones a transverse slice several millimeters thick was taken across the ovary at its widest point. In large ovaries and fruits, a segment of this region from the outside to the center, or samples of the various tissues in such a segment, were collected. Part of the material was killed in formol-aceticalcohol, part in Carnoy's solution, and part in Craf, the last giving the best results. Material was embedded in paraffin and transverse and longitudinal sections cut. Haematoxylin stains, chiefly Heidenhain's, were used, since they best brought out the cell walls.

Cell diameter in the transverse plane was especially studied and was compared with organ diameter in the same plane. Since the cells in the tissues studied were found to be essentially isodiametric, cell volume could be determined in relation to fruit volume; but the essential facts were obtained most simply by a study of transverse diameters.

Anything like an accurate measurement of cell size in a mass of tissue is beset with difficulties, which the writer does not wish to minimize; but if care is used in obtaining data, if large numbers of cells are measured, and if the results are consistent and fall into a fairly simple system, the investigator may be confident that he is not far from the truth. The method used in the present study was to draw cells with a camera lucida or a projector at known magnifications and to measure the drawings, computing from these the actual sizes. The most difficult problems here were to determine where to make the measurements and which cells to measure. In all races there is a gradient in cell size from the inside of the ovary outward, the cells growing progressively smaller toward the epidermis. Measurements were made at a number of points along this gradient. Several regions may readily be distinguished:

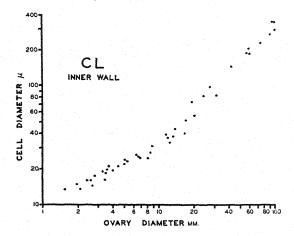

Fig. 1. The relation of cell diameter to fruit diameter in the inner wall of Race CL. Each point represents the average of 20 measurements. Both variables are plotted logarithmically.

the central placental region, normally consisting of three ovule-bearing sections; the inner wall, between the outside of the placental region and the ring of twenty main vascular bundles; the outer wall, between these bundles and the epidermis; and the epidermis itself. In all the genera except Lagenaria, two definite layers can be distinguished in the inner wall: an innermost one in which the phloem strands run lengthwise of the ovary, and an outer one where they run at right angles to this, or tangentially. These layers are called the "inner" and "middle" layers in these types. The morphological nature of the peripheral tissues in the ovary and fruit of this family seems not to be well established and for this reason the non-committal word "wall" is here used.

Definite points were chosen in these various layers at which cell sizes were measured. These were as follows: (1) the area near the axis of the placental region, just outside the point where the three carpels come together; (2) an area half way radi-

ally across the inner wall; (3) an area half way across the middle wall; (4) an area half way across the outer wall; and (5) the epidermis. In Lagenaria, of course, there were only four points of measurement since here (2) and (3) are indistinguishable. In this genus the region chosen here was half way from the placenta to the bundles. In most races cells were also measured in the region between two bundles and thus intermediate between the middle and outer walls; and also in the hypodermal layer, just under the epidermis. For a number of reasons uniform measurements were difficult to make here, however, and the data are not included in the present paper.

Even in these very definite regions there are considerable variations in apparent cell size. Some of these are due to the fact that the cells have been cut at various levels and thus appear to have somewhat different diameters. A much more important cause, however, is that throughout early developmental stages cell division is taking place, so that small cells, resulting from recent divisions, are intermixed with larger ones which have expanded considerably. In all tissues, however, if occasional abnormally large cells are disregarded, a common maximum size can be distinguished which is characteristic of the whole area and is apparently the cell size at which, in this region, division will again take place. These are the cells which were chosen for measurement, and with a little practice they can rather readily be picked out. For each of the five (or four) tissue regions in each ovary studied, twenty of the typical cells were drawn on a single sheet. Among these the ten least extreme in size and shape were chosen, and in each of these the longest and shortest diameters were measured. The average of the twenty measurements was then taken, after correction for magnification, as the cell diameter for this tissue. The fact that cell measurements made in this way by four persons yielded very similar and consistent results indicates that the method is a dependable one and that the data are trustworthy.

The most satisfactory method of analyzing the relationship between cell size and organ size during development is to plot one variable against the other at as many stages in growth as possible. Since growth is an exponential process, it is much more satisfactory to plot the logarithms of these values rather than the values themselves. This makes it possible to compare small and large members of a series on an equal basis. In practice, the values were plotted on double logarithmic paper, with cell diameters on the ordinates and ovary diameters on the abscissae.

RESULTS.—General relations of cell size to organ size.—In figure 1 are shown the data, plotted on a double logarithmic grid, for the inner wall of Race CL, a "Club" type of Lagenaria. Each point represents the average of twenty measurements of cell diameter in this tissue, in an ovary of the diameter indicated. It will be observed that from the smallest sizes, with an ovary diameter of about 2 mm.,

these points form a rather narrow band which is essentially linear and which rises with a slope of about 45 per cent. This indicates that cell diameter increases as ovary diameter increases, but only about 45 per cent as fast. In other words, the value of the relative growth constant (a in the allometric formula of Huxley and Teissier, 1936) is .45. In ovary diameters greater than 12 mm. this relationship changes markedly, the band bending upward sharply to a value of about 1.0, which is maintained to the end of growth. Evidently after the attainment of an ovary diameter of 12 mm., cell diameter and ovary diameter are increasing at equal rates. To facilitate more exact comparison of these growth relationships, a line may be drawn through the center of the band. It will consist of two linear portions meeting at the point of inflection. This has been done in all later figures.

The fact that in early development ovary width is growing faster than cell width can be explained only by assuming that cell number must here be increasing. Since beyond the point of inflection both cell and organ increase equally, there is evidently no increase in cell number here. The inflection point thus indicates (subject to a correction discussed below) the approximate ovary and cell diameter at which, in this tissue, cell division ceases. Before this point, growth is the result both of cell multiplication and of cell enlargement. After this point is reached, it is the result of cell enlargement only.

Two features of this developmental relationship between cell size and organ size are noteworthy. First, there is evidently a considerable increase in cell volume even during the period when cell division is going on. This must mean that there is no fixed size at which cell division occurs but that after each successive division the two daughter cells, before they themselves divide again, increase to a size considerably greater than that of their mother cell at the time of its own division. Second, the fact that the inflection point is sharply marked and that the line leading up to it is straight rather than curved indicates that division stops suddenly rather than gradually, and that the rate of division is constant and is independent of the size of the cell. Thus cells with a volume of 30,000 cubic micra apparently divide as rapidly as those of 1,000 cubic micra, a rather remarkable fact, since larger cells might be supposed to divide less rapidly than smaller ones.

The cessation of division is associated with the attainment of a definite cell size. This size is evidently a matter of some significance in the developmental process. It is evidently not exactly the size at the inflection point but a somewhat lower value. Increase in cell size is not a continuous process but is interrupted at each cell division, for cell volume is then reduced by half and cell diameter by slightly more than 20 per cent (logarithmically by approximately .1). Each daughter cell now increases (at the same rate as the whole tissue) to a somewhat greater diameter than that of its mother cell and then divides again. Thus the changes in size in a given cell

lineage are not to be represented by a continuous line but by a serrate one (fig. 2). The line shown in the figures in the present paper is that which connects the tips of these "teeth," since we have endeavored to measure the cell diameter at its normal maximum before each division. After the last division, cell enlargement proceeds continuously, uninterrupted by further breaks, at approximately the same rate as fruit enlargement. The cell diameter at the last division is therefore that at the tip of the

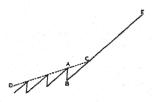

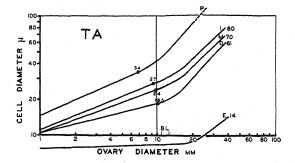

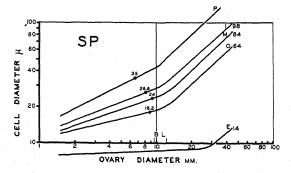

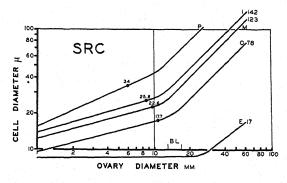

Fig. 2. Diagram showing how cell diameter (ordinates) changes in relation to ovary diameter (abscissae) in a single cell lineage for a given tissue. A. cell diameter at the last division. B. diameter of a daughter cell at its formation. C. inflection point. The line D-C-E represents those shown in fig. 3-14.

last "tooth," or the point at which the diameter of a cell half as large (and thus with a diameter slightly less than 80 per cent as great) will fall on the downward prolongation of the second part of the growth line, after the inflection point. Thus in figure 2, C is the inflection point, A the diameter at the last division, and B the diameter of the last daughter cell at its formation. This cell now becomes greatly enlarged. This method of determining the cell diameter at the last division can be checked by direct observation. Mitotic figures are not numerous, but they can be found, and the largest cells in which these occur, in a given tissue, are of approximately the size thus calculated. Furthermore, tissue in which division is still going on can usually be recognized by the occurrence within it of obviously new cross walls separating what were the two halves of a recently divided cell; and the point at which division ceases, as indicated in this way, gives a good general agreement with the other methods.

For the twelve races analyzed, the relation of cell size to ovary size was determined for each tissue and from small ovaries to mature fruits, and the results were essentially the same as in the example just described. A line was drawn through the middle of the band of points in each tissue, and the lines for the various tissues in a given race were all plotted on the same double logarithmic graph. The results are presented in figures 3 to 14. In a few, analysis begins with ovaries of 1 mm, in width, but in one the smallest was 2.5 mm. The average diameter at the start of observation was somewhat less than 2 mm. The cell diameter at which the last division occurs, as determined by the method first outlined above, is shown by a black circle, and the value in miera indicated above or beside this. The cell diameter at maturity, in micra, is also given. The lines for the pla-

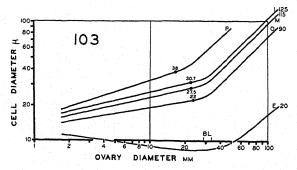

Fig. 3-6.—Fig. 3 (top). Cucurbita Pepo, Race TA.—Fig. 4 (second). C. Pepo, Race SP.—Fig. 5 (third). C. Pepo, Race SRC.—Fig. 6 (bottom). C. Pepo, Race 103. Graphs showing relative growth of cell diameter to ovary diameter for all tissues in the twelve races are shown in fig. 3-14. Each line has been drawn through the middle of a band of points similar to that shown in fig. 1. Solid circles, cell diameter at last division. Values given are for cell diameters in micra at the last division and at maturity. P, placental region. I, inner wall. M, middle wall. O, outer wall. E, ep.dermis. BL, flowering size.

cental region, inner wall, middle wall, outer wall, and epidermis are indicated by the letters P, I, M, O, and E, respectively. Cell diameter at any fruit diameter may be approximately determined from these graphs. In table 1 are given the actual values for the cell diameters of the various tissues at two convenient ovary diameters (2 and 10 mm.), at the point of last division, and at maturity. The relative growth constants for cell diameter against ovary diameter, during the period of cell division, are also given.

Differences between tissues.—A study of the developmental cell-organ size relationship in these twelve races shows that in all of them the various tissues (except the epidermis) behave in essentially the same way as in the example given above for the inner wall of Race CL, a period of cell division and slight expansion changing rather suddenly to one of expansion only. Although this is the general procedure, there are certain consistent differences between tissues in the same race, and between different races, which are significant.

The most obvious difference between tissues is in the rate at which cell enlargement takes place during the period before division ceases. Since the lines for the various tissues diverge, under logarithmic plotting, it is evident that the cell size differences between them are becoming not only actually but relatively greater. In other words, differentiation is occurring. Thus between an ovary width of 2 mm. and 10 mm., the placental cells on the average increase in diameter about 100 per cent but those of the outer wall only about 30 per cent. Furthermore, in every race there is a gradient in cell increase, each successive tissue, from within outward, showing a lesser rate of increase than the one inside it. In races where measurements were made for the bundle region and for the hypodermal region, these were found to occupy their expected positions in this gradient-namely, between the values for the middle and outer wall and between those for the outer wall and epidermis.

A somewhat similar gradient exists in the time at which cell division ceases. This typically occurs first in the placental region and successively later in the more outer tissues. The difference between the tissues in this respect is much greater in some races than in others, but the order is the same.

A third difference is in the cell size at the last division. This is typically greatest in the placental region and successively less in the outer ones. In a number of instances these outer tissues continue to divide until they approach the same cell size that the placenta had at its last division, but some difference always remains.

The epidermis is the most extreme of the tissues in all three of these respects. Its cells increase but little in size and in some races may actually decrease for a time. The inflection point occurs very late, showing that division persists much longer than in other tissues. Cell size at the last division is very small. The inflection point is not sharply marked,

as elsewhere, and the slope of the line following it often does not reach a value of 1.0 for some time, so that cell division evidently does not cease here as suddenly as in the other tissues. The dimension of the epidermal cells here given is the periclinal (tangential) one, which is essentially the same as the longitudinal dimension, since the cells, seen in surface view, are isodiametric. The anticlinal or radial dimension usually follows about the same course as the periclinal but is somewhat greater in absolute size. It pursues a slow but steady increase without a marked inflection point, doubtless because cell division does not occur in the tangential plane and the "saw tooth" type of growth is absent.

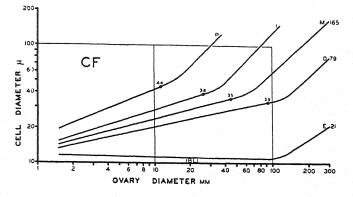

In all tissues the second growth period, in which cell expansion alone is occurring, shows an approximately equal growth rate of cell and ovary, although this varies somewhat, since the various tissues do not grow at the same rate as the ovary as a whole. In the innermost tissues, especially of large-fruited races, the cells die and collapse before fruit maturity is attained.

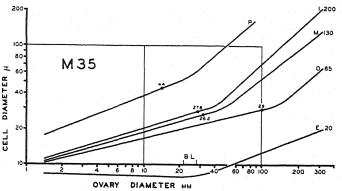

It will be observed that the lines for all the tissues of a given race, if projected backward, tend in most cases to converge to a common point of origin. This is usually at a cell diameter in the vicinity of 10 micra and an ovary width of something less than 1 mm. This cell dimension is not always that of the actual meristem, but of the ovary primordium when differentiation among its tissues begins. The early history of the ovary, reconstructed in this way, is only an approximation, for at smaller sizes than 1 mm. analysis is difficult.

Differences between large-fruited and small-fruited races.—The general relation between cell size and organ size during development is much the same in the twelve races studied, but there are a number of significant differences observable which throw some light on the developmental mechanism by which fruit growth is accomplished.

These differences can best be studied in the seven races of Cucurbita Pepo. Three of these, TA (fig. 3), SP (fig. 4), and SRC (fig. 5), have small fruits, from 40-65 mm. wide. Three others, CF (fig. 7), M 35 (fig. 8), and MT (fig. 9), are much larger, with fruits over 300 mm. in diameter. Race 103 (fig. 6) is intermediate in size. The analysis of these races as shown in the graphs makes it possible to compare the development of a small fruit with that of a large one in at least six respects, as follows:

(1) It is clear that there are no significant differences in initial cell size in the young ovary between large-fruited and small-fruited types. At an ovary diameter of 2 mm., the former have an average cell

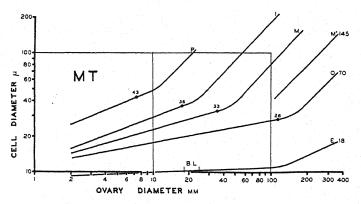

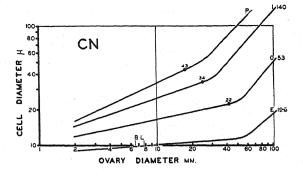

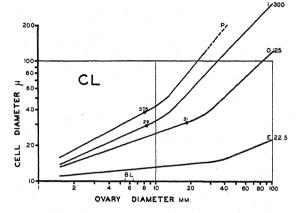

Fig. 7-9.—Fig. 7 (above). C. Pepo, Race CF.—Fig. 8 (center). C. Pepo, Race M35.—Fig. 9 (below). C. Pepo, Race MT.

diameter for all tissues about 5 per cent greater than the latter. At an ovary diameter of 10 mm., however, the small races have cells about 2 per cent wider than the large ones. Cell size at the meristem has not been studied, but it seems doubtful if there is any fundamental difference here.

(2) During the period of cell division, the small-fruited races have a generally higher relative rate of cell enlargement compared to ovary growth, as is shown by the somewhat steeper slope of their lines. For every tissue, the average value of this relative growth constant is higher for the three small-fruited races than for the large ones, the general average for the former being 34.7 as against 30.9 for the

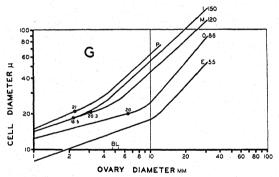

Fig. 10-12.—Fig. 10 (above). Lagenaria vulgaris, Race CN.—Fig. 11 (center). L. vulgaris, Race CL.—Fig. 12 (below). Cucumis Anguria, Race G.

latter (table 1). This means that a given cell size is reached at a somewhat smaller ovary size in the small-fruited types than in the large ones. If cell division ceases at the same cell size, it will therefore evidently be prolonged somewhat in ovaries of the large types, a larger number of cells will be produced, and a correspondingly greater fruit size attained at maturity. It can readily be calculated that the increase in fruit diameter due to this cause alone is about 30 per cent.

(3) Another difference between large and small types is the fact that in the former, the cell size at which division ceases is considerably greater than in the latter. For the four tissues in which it was determined, the average cell diameter at the last divi-

sion was 34.75 micra for the large-fruited races and 25.63 micra for the small ones, indicating a difference of more than two and a half times in volume. This means that cell division persists markedly longer in the former than in the latter, with a corresponding increase in cell number and thus in fruit size. An ovary with the final cell size which is the average for the three large races would thus have a diameter, due to this plus the relative cell-organ growth rate difference, more than three and a half times that of one with the average values for the three small races, and would have a volume of ovary and fruit more than 45 times as great.

(4) The situation is complicated, however, by a fourth difference between large and small fruitsnamely, the total duration of cell division. Division ceases first in the inner tissues and later in the successively outer ones; but in the small-fruited types this all occurs within a relatively short period. whereas in the large ones it is spread out over a much longer one. Thus in Race TA, division ceases in the placenta at an ovary diameter of 6.9 mm. and in the outer wall at 10 mm.; in SP these values are 6.5 and 9.0, and in SRC, 6.0 and 10.5 mm. Division thus ceases rather abruptly, except in the epidermis. In CF, on the other hand, division in the placenta ceases at 11.5 mm. and in the outer wall at 92; in M35 the range is from 14.5 to 100, and in MT from 7.3 to 115 mm. The period is over five times as long, logarithmically, in the large races as in the small ones. In the former the various tissues tend to approach the same cell size before division ceases, although this is never quite attained. In the latter there are markedly greater differences in cell

This much greater duration of cell division, and the consequently larger number of cells produced, is evidently a major factor in determining the greater fruit size of the large types. It might be thought possible to determine the actual increase in cell number for each race by dividing organ size by cell size in the various tissues. This cannot be done accurately from the data here presented, however, since the various tissues are increasing at different rates and since cell size should be compared with its particular tissue volume to make a calculation of cell number possible.

size when division ceases.

(5) The amount of cell expansion, following the cessation of cell division, tends to be considerably higher in the large-fruited types. In all races the placental cells, which are the largest from the start and begin to expand first, collapse before fruit growth ceases. The relatively very great enlargement which they would undergo, if they continued to expand to the end, is too much for their powers of enlargement, and they die, become filled with air, and finally are pulled apart and disintegrated by the continued growth of the outer layers. In large types the whole inner placental region disappears, and the mature fruit is hollow.

The wall layers all survive to maturity in the small types, but in the large ones the inner wall usu-

ally breaks down and sometimes the middle wall as well. This is due to the fact that division extends over such a long period here that the inner layers have to expand very greatly if they are to persist. In Race MT there arises around each phloem strand in the middle wall a group of small cells. As the primary cells of the wall enlarge and collapse, these secondary ones expand and fill their place. This produces the stringy, fibrous character of the wall evident in coarse-fruited types of this sort, as compared with the much more homogeneous character of fine-textured races like M35.

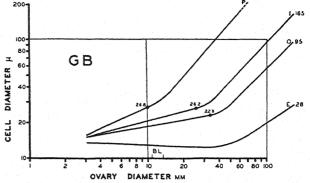

Race M35 is the only large type in which cell size can be compared with the small-fruited races. It is evident that in inner and middle walls its cells are much larger. Even though the inner lavers in the other races do not persist to maturity, they expand considerably further before collapsing than the final size in the small-fruited types. The outer wall in the large types, doubtless since it begins its expansion so late, usually does not have larger cells than those of the small races. The epidermal cells are considerably larger, however. It is clear that large fruits have consistently larger cells at maturity than small ones and that this is due partly to larger cell size when division ceases, but chiefly to the greater expansion which their cells then undergo.

The important part which cell size differences often play in determining

fruit size is also well shown by a comparison of the three small races. They have very similar developmental schedules up to the time when division ceases but vary considerably in the amount of later expansion, TA having least, SP next, and SRC most. The final fruit size is almost directly proportional to the amount of cell expansion, and difference in fruit size among these races is therefore related primarily to differences in cell size rather than in cell number. TA with as much cell expansion as SRC would produce a very similar fruit.

(6) Another point of general difference between large and small types is in ovary size at flowering. This is consistently larger in the large types, with an average diameter of about 22 mm. as compared with about 11.5 mm. in the small ones. Thus at a comparable stage of development the large types have larger ovaries, with larger cells and a higher degree of differentiation. At comparable stages from the beginning, the large-fruited types are somewhat larger.

Race 103 occupies an intermediate position between the large and the small races, in mature fruit size. This seems to be due primarily to the fact that in early development cell enlargement is relatively

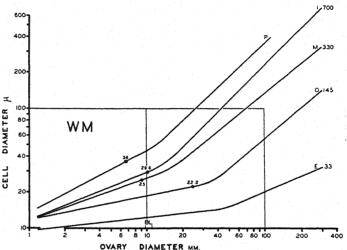

Fig. 13-14.—Fig. 13 (above). Lagenaria vulgaris, Race GB.—Fig. 14 (below). Citrullus vulgaris, Race WM.

slow as compared with cell multiplication, so that the relative growth ratios of cell to ovary diameter are the lowest of any race. This, together with a slightly higher cell size at the last division, results in a very large number of cells. Race 103 in other respects resembles the small races, for cessation of division in all tissues occurs almost simultaneously, and the amount of cell expansion afterward is relatively very small. In its earlier development, 103 resembles the large-fruited races; later, it resembles the small ones. Evidently the various elements determining final fruit size are independent of each other and may be combined in various ways.

Other genera.—The three races of Lagenaria vulgaris analyzed differ rather markedly among themselves.

Race CN has a relatively large cell size when division ceases and a long period of cell multiplication, but the extent of later cell expansion is relatively slight so that final fruit size and cell diameter are small. Like Race 103, in early development this resembles a large-fruited race and later a small one. Conditions are exactly reversed in Race GB, for here the cell size when division ceases is usually small so that the duration of cell multiplication is less; but the amount of expansion is great, with the

result that both fruit size and cell size at maturity are relatively large. GB differs from all other races in the comparatively large ovary size attained (about 2.5 mm.) before differentiation in cell size begins.

Race CL is distinguished by its relatively high rate of cell enlargement in early development, its values being higher (its lines steeper) than in any other type studied. As a result, cell multiplication ceases relatively early, in terms of ovary diameter. and although cell expansion is extensive, the fruit is only a little more than 100 mm. wide at maturity. These facts can be understood in the light of the unusual development of this race, for here, unlike the others, width grows much more slowly than length. Early cell increase is rapid as compared to ovary width, but as compared to ovary volume it is much as in the other races. A given ovary diameter here represents a considerably later developmental stage than in races where length and width increase at nearly equal rates.

Race G, a type of Gherkin, Cucumis Anguria, is the smallest of those studied and has, as might be expected, the lowest cell size at the time when division ceases. Unlike the small-fruited Cucurbita races, however, this size is almost the same for all tissues. Cell multiplication ceases relatively early, and although expansion after division ceases is great, the final fruit diameter is only a little more than 30 mm. Another striking difference between this race and all the others is in the epidermis, which increases steadily from the beginning and has a definite inflection point and a later period of rapid expansion. It thus behaves much like the placental and wall tissues.

Race WM, a watermelon, is chiefly notable for its enormous cell expansion. Even in early development its rate of cell expansion is relatively high, and since cell size at the cessation of division is not great, division stops early. In this respect WM resembles the small-fruited types of Cucurbita. The amount of later expansion is so great, however, that a large fruit is actually produced. The placental cells break down, but the inner wall cells reach the surprising diameter of 700 micra, and in other types even this is exceeded. These large cells seem still to be alive. They have increased to about 350,000 times their meristematic volume.

Discussion.—There are evidently many developmental differences between fruits of different races.

Not only are large-fruited types different from small ones in many respects, but even the same fruit size may be reached in different ways. The determination of fruit size clearly involves many distinct and apparently independent processes. The genetic basis of size differences therefore involves not a single series of growth intensities but many separate physiological processes which seem to be inherited independently. It is not surprising that genetic analysis shows size characters to be dependent on many genes.

The problem of the relation between cell size and organ size is evidently not a simple one but involves all aspects of the growth and differentiation of a determinate organ. It is but one part of a complex developmental problem. The various processes which have been shown here to be concerned in fruit growth will now be more fully discussed.

The rate of cell division and the rate of cell expansion are obviously the two most important of these. No data are here presented as to absolute rates of either, but other evidence, showing that fruit size is not related to growth rate, indicates that there are no very great differences between races in either the frequency of division or the rapidity of expansion. It is clear, however, that considerable differences exist in the relative rates of these two processes, not only between races but especially between tissues, as is shown by the differences in the relative growth constants for cell size against organ size. Where this value is positive the cells increase in diameter, indicating that expansion is more rapid than division, in the sense that the cells expand between divisions to a greater size than their mother cells. An important fact, not sufficiently recognized in discussions of the problem of size, is that a given cell size is merely the resultant of the frequency of cell division as compared with the rapidity of cell expansion. Large cells indicate either fewer divisions, more expansion, or both.

What causes the pronounced differences between internal and external tissues in the relative rates of these processes is not clear. Evidence to be presented elsewhere, however, indicates that rate of cell division is essentially the same in all tissues and that the differences here described are chiefly in rate of expansion. The definite gradient from within outward in this respect suggests a corresponding gradient in respiration rate, osmotic concentration, permeability, pH, or amount of some growth substance.

It is significant in this connection that Gustafson (1939) has recently found a higher concentration of auxin in the central region of a squash fruit than in its wall.

Related to this may perhaps be the other gradient-namely, that in the time of cessation of cell division. This event occurs first in the innermost tissue and progressively later in the outer ones. The facts suggest a gradient in the amount, or in the rate of consumption, of some material essential for cell division which is thus exhausted first in the inner tissues and last in the epidermis. Where this gradient was slight, cessation would occur at almost the same time in all tissues, as was found to be the case in the small-fruited races of Cucurbita. Where it was steep, division in the outer tissues would persist for a progressively longer period, as was found to be true in large-fruited races. These two gradients, whatever the causes for them may be, are evidently of much importance in the problems of both cell size and organ size.

It is evident that there is no fixed cell size at which mitosis occurs, even in the same tissue. Except in the epidermis, successive cell divisions are at progressively larger cell sizes. Division ceases at widely different cell sizes in different tissues. We must look for something other than the attainment of a specific cell size as the factor which initiates mitosis or which finally stops it. Cell size, however, does seem to play some part in the cessation of division, for there is usually a rather definite upper limit beyond which division will no longer take place. After a diameter of about 45 micra, when the cell has become vacuolate, further division is obviously difficult. But the limit is often reached much earlier than this, as in Race G, where in no tissue does it much exceed 20 micra. Perhaps the most remarkable fact, already mentioned above, is that the rate of cell division seems to be the same regardless of cell size. Since the duration of cell multiplication, and thus the number of cells produced, is so closely related to the determination of organ size, the problem of the factors—chemical, physical or otherwise -which initiate or inhibit cell division is evidently of much significance here.

What part the attainment of sexual maturity or flowering may have in these developmental processes is not very clear. In the races of Cucurbita, Cucumis, and Citrullus studied this occurs not long after cell division ceases in the placental region and is perhaps associated with a given stage in the development of the ovule-bearing tissues. This relationship is not so clear in Lagenaria. In the small-fruited races of Cucurbita division in all tissues but the epidermis has just finished when flowering occurs, but in the larger ones, division in the wall layers persists long afterward.

Various factors suggest themselves in explanation of the differences in amount of cell expansion following the end of division. In most types the cells are incapable of living, and their walls of expansion, after a diameter of about 200 micra is attained. In

watermelon, however, the cells are so constructed as to undergo far more expansion than this. Some small types, on the other hand, cease to enlarge at relatively small sizes. Whether these differences are due to different amounts of some substance which affects the extensibility of the wall, as auxin has been supposed to do, is a matter for investigation. There is some evidence that a more important factor in limiting the amount of expansion is the deposition of the secondary cell wall, which soon becomes so strong that further enlargement is impossible. The fact that it is commonly those types (notably the small-fruited forms) with the least amount of cell expansion which become the most hard and woody at maturity, and the ones with relatively great cell expansion which tend to remain soft (like the pumpkins and watermelons) seems to indicate the importance of secondary wall formation in limiting growth. Quite apart from either of these factors, the concentration of cell sap and the general expansive power of the cell may possibly be of much importance in determining how far it will enlarge.

The rather wide differences in amount of cell expansion, together with the variations in cell size at the last division, result in a good deal of variation in cell size at maturity even in closely related races, larger cells generally being associated with larger fruits. This conclusion is at variance with that of Sachs and Amelung. Indeed, with so many factors operating in determining cell and fruit size, it would be remarkable if cell size always ultimately reached the same value and if fruit size differences were due entirely to differences in cell number.

The relations between cell size and organ size here described apparently hold in other parts of the plant, such as the petiole (Sinnott, 1930). In the fundamental tissues of most axial organs there is a descending gradient in cell size from within outward which would probably show the same developmental history as that described here for the fruit. Analysis is more difficult in such organs, however, since the duration of growth is relatively short.

We may conclude that the relation of cell size to organ size is a complex one and that it is intimately involved with the whole developmental process. It cannot be solved merely by comparing the sizes of the two structures at maturity, as has usually been the procedure. A careful descriptive analysis of the whole course of development in quantitative terms is first necessary, not only to discover how the relations which are found at maturity have arisen but to distinguish the various processes which are concerned in growth and differentiation. This will open the way for an experimental study of each of these processes and thus for an ultimate attack on the whole problem of development.

### SUMMARY

In twelve races of cucurbits belonging to four genera, cell diameter was measured in a series of tissues from the central region of the ovary to the outside and at many stages during the developmental period from very small ovary primordia to mature fruit.

In each tissue growth takes place at first chiefly by cell multiplication, though cell size slowly increases also. After a specific cell size is reached. division ceases, and all further growth of this tissue is by cell expansion.

The innermost tissues, as compared with the successively outer ones, show (a) more rapid increase in cell size during the period of cell division, (b) earlier cessation of division, and (c) greater cell size at the time when division ceases.

In Cucurbita Pepo, large-fruited races as compared with small-fruited ones typically show (a) no difference in cell size during early development; (b) a more extended period of cell division, due to less rapid increase in cell size, greater cell size at the time of last division, and a greater interval between the cessation of division in successive tissues; and (c) greater cell expansion after cell division ceases.

Differences in fruit size are therefore usually due to differences in both cell number and cell size, though either factor may alone be responsible in certain cases.

Specific differences in development between Cucurbita and the three other genera are described.

Possible factors responsible for the differences in cell division and in cell expansion between the various tissues and in the various races are discussed.

The problem of the size relation of cell to organ is part of the more general problem of the factors determining growth and differentiation. The first step in the solution of this problem is a thorough descriptive analysis in quantitative terms.

### AUXIN DISTRIBUTION IN FRUITS AND ITS SIGNIFICANCE IN FRUIT DEVELOPMENT 1

Felix G. Gustafson

GROWTH SUBSTANCES or auxins, as they will be called in this paper (Went and Thimann, 1937), are now generally considered to be factors in vegetative growth of plants. Recent investigations on artificial parthenocarpy produced by chemicals (Gustafson, 1936; Hagemann, 1937; Gardner and Marth, 1937) have shown that auxin under artificial conditions can also cause fruit development without fertilization. This coupled with the fact that auxin has been shown to be widely distributed in the vegetative parts of plants leads one to assume that auxin is also concerned with normal fruit growth. Gustafson (1939) has proposed the theory that a high auxin content in the ovary in the flower bud stage is responsible for natural parthenocarpy, which is found

1 Received for publication December 15, 1938. Paper from the Department of Botany of the Univer-

sity of Michigan, No. 682.

The writer wishes to express his thanks and appreciation to F. W. Went, E. G. Anderson, J. Van Overbeek, and William S. Stewart, of the California Institute of Technology, and to William Hertrich of the Huntington Gardens, San Marino, California, for various aids extended during the course of this investigation and to the Directors of the Horace H. Rackham Trust Fund of the University of Michigan for financial aid.

in many plants. In this paper it was shown that the auxin content is actually much higher in the ovaries of those plants that produce fruits parthenocarpically than in similar varieties requiring fertilization for fruit production.

Before it is possible to proceed very far with this matter, it is first necessary to investigate the auxin distribution in fruits. In 1936 Dollfus published some experiments which tended to show that auxin is produced in the developing seeds. He used the diffusion method. In these experiments he found that a substance diffused from the ovules into the agar which caused Avena coleoptiles to curve, but no such substance diffused out of the outer part of the ovary. Meyer (1936) has also found auxin in fruits. He extracted the auxin with alcohol in a reflux condenser for two hours and mixed the extract from 10 grams of fresh material with 1 gram of lanolin, which was applied to one side of intact Avena coleoptiles. While this method is perhaps not so good as the method in which agar containing the auxin is applied to decapitated etiolated Avena coleoptiles, nevertheless it is fairly accurate. In these experiments Meyer used a number of species of plants, and in the fruits of all these species he was able to demonstrate the presence of auxin. He did not do much with the distribution within the fruits, but in the few determinations he made, seed material gave a greater Avena coleoptile curvature than the other parts of the fruit.

The present work was undertaken to investigate further the auxin distribution in fruits. Fruits from many plants, in different stages of development and

during different seasons, were used.

PROCEDURE.—The work here reported was done at the William G. Kerckhoff Laboratories at the California Institute of Technology. Part of the experimental material was grown especially either in the greenhouse or in the field, while some of it, as the Yucca Whipplei, Agave Brundigii, Pittosporum undulatum, and Clivia sp., was obtained from the Huntington Gardens at San Marino. The auxin content and distribution was determined by the Avena method, the technique of which has been discussed in detail by Went and Thimann (1937).

Auxin was extracted with freshly distilled ether according to Van Overbeek's (1938) modification of other methods. The dried residue was thoroughly mixed with a known amount (usually .4 to .8 cc.) of 1.5 per cent agar and after standing 90 minutes was poured into a nickel plated brass mold 1.5 imes 8.0 imes10.5 mm. in size. After the agar had been cut level with the surface of the mold, the large block was cut into 12 equal pieces. The material was now ready for the test. Great care was taken to have freshly prepared extracts. Usually the extract was prepared the same day that it was used, but if the extract could not be used the same day that it was made, it was always stored in a refrigerator in dried condition. Fleshy material was repeatedly extracted until the Avena test plants showed no curvatures when treated with the agar-extract. In some experiments such material as tomato and squash was first frozen with liquid air then ground in a mortar and the ether added. The extraction was always carried out in the dark and usually, though not always, at a low temperature.

Control experiments in which Avena plants were treated with a known concentration of indole acetic acid (usually 21.5 gamma per liter) were run with every experiment. (This concentration ordinarily gave a curvature of about 10-12°.) By this means the sensitivity of the test plants was determined for each experiment, which was very important, because there was considerable variation day by day, and the auxin concentration in a plant can be calculated in terms of indole acetic acid (see Van Overbeek) rather than in terms of some of the many units which have been employed by different investigators. This procedure has the advantage that the activity of the growth substance or substances is recorded in terms of a known and easily obtainable substance, indole acetic acid. One does not know what the substance is nor is its concentration known, but it is known that its activity on a decapitated Avena coleoptile is equal to a known concentration of indole acetic acid.

A few experiments were performed in which the plant material was placed on the agar blocks as in Went's original experiments. In most instances such blocks when placed on Avena coleoptiles caused no curvatures. It had been hoped that this method could be used, but as so few plants gave any results, it was abandoned for the extraction method. This brings up a question which is in the minds of manynamely: Is extracted auxin the same as that which diffuses into the agar block, and if so, is the concentration in the plants that give negative results so low that only by using a large quantity of material can a test be obtained; or is the auxin which is obtained by extraction released from a combined form, with low diffusibility, by the extraction treatment? Those experiments in which, by daily extraction, active material continued to be obtained for a period of 10 days certainly suggest an affirmative answer to the latter alternative.

In these experiments the fruits were separated into an interior and exterior part, or, as in the tomato and summer squash, further subdivisions were made. When a fruit was divided into only two parts, the interior part included the central axis, the placentae, the ovules and all the cells in between and immediately surrounding the ovules, and the exterior part usually included only the ovary wall, as in the peppers, tomatoes, beans, and Yucca. In the second experiment with peppers, listed in table 1, the beans and Yucca, only the ovules and seeds were included in the interior part. The extraction method varied considerably in these experiments. All material was cut into rather small pieces to begin with, but in some experiments these pieces were frozen with liquid air, and while they were in the frozen condition, attempts at maceration were made. These differences in treatment of the material should in no way influence the results, as all material experimented with at any one time was always treated in the same way, and extractions were continued until no further reaction was obtained with the Avena coleoptiles.

The investigation was divided into two parts. Part one dealt with the auxin distribution in nonparthenocarpic fruits, and the second part with a comparison of auxin concentration in artificial parthenocarpic and non-parthenocarpic fruits. In the second part the same plants were used, and the extractions were of course made at the same time.

RESULTS AND DISCUSSION.—Distribution of auxin within non-parthenocarpic fruits.-In determining the auxin distribution within fruits, a number of different plants were used, and the experiments extended over a period of five months from March to August. The differences in auxin contents that have been noted in different experiments with the same species of plants are probably partly due to seasonal differences and partly to difference in the vigor of the plants. The tomatoes in table 1, the first experiment with peppers in table 1, and all the peppers in table 5 were grown in the greenhouse during the winter or early summer, and the plants

Table 1. Auxin distribution within fruits. The interior includes only ovules or seeds in Yucca, beans, and the second experiment with peppers; otherwise it includes the central axis, the placentae, ovules, and all cells in between or closely associated with them. Figures denote auxin concentration in terms of indole acetic acid equivalents in gammas per kilogram green weight, except in the diffusion experiment with Pittosporum. The second experiment with peppers, the experiments with cucumbers, crookneck summer squashes, and beans were made during the summer, and the others during the winter or spring.

were not particularly vigorous, while the second experiment with peppers employed fruits grown in the field, where the plants were much more vigorous. The fruits were also larger. Even though there was considerable difference between different lots of fruits, the relative concentrations within the fruits were much the same in all experiments with the same fruit. The auxin concentration was much lower in the winter and spring than in the summer.

From the information gained in these experiments Yucca in which only seeds or ovules were used. In it seems as if the seeds or developing seeds must be centers of auxin production. This is particularly indicated by the experiments with peppers, beans, and the other fruits other cells adjoining the seeds were used, and the results are not so positive for them. To clear up this point, crookneck summer squash and tomatoes were used in several experiments in which the seeds were separated from the rest of the fruit, which was further subdivided.

Table 2. Auxin distribution in fruits of tomato and crookneck summer squash. Auxin concentration is denoted in terms of indole acetic acid equivalent, and the figures denote gammas per kilogram of fresh material. These experiments were made during the summer.

In two experiments tomato fruits were separated into five parts and these parts extracted separately. Included in one of these experiments were parthenocarpic fruits produced by phenylacetic acid. Phenylacetic acid is known to give practically no Avena test, and therefore fruits were produced by its stimulation to determine whether these parthenocarpic fruits make or at least contain auxin. Table 3 gives the result of these experiments.

These experiments show that the ovules or young seeds are high in auxin content and that the other parts of the fruits contain much less auxin. Whether this auxin is produced in the ovules or diffuses into them from the leaves, we have no way of knowing from these experiments. Nevertheless, the results as a whole indicate that growth (however initiated) sets up a concentration gradient with the highest concentration in the ovules, when present, otherwise in the central axis and partition region and with a low concentration in the ovary wall.

Table 3. Auxin distribution in tomato fruits, produced by pollination and parthenocarpically by by phenylacetic acid. The fruits were green and between 4.5 and 6.0 cm. in diameter. Auxin concentration is denoted in terms of indole acetic acid equivalent, and the figures indicate gammas per kilogram of fresh material. These experiments were made during the summer.

Type of fruit Seed	Jelly around seeds or ovules	Placentae	Central axis and partitions	Pericarp
Normal (Exp. 57) 15.33	6.57	2.44	2.27	1.27
Normal (Exp. 65) 30.05	0.45	2.47	2.69	0.63
Parthenocarpic (Exp. 65)	1.25	0.49	6.42	0.81

Comparison of auxin content in parthenocarpic and normal fruits.—In the preceding section it has been shown that the ovules or seeds of fruits have a high auxin content. In order to answer some of the questions which have been raised concerning the growth of fruits, it is necessary to know whether or not there is auxin production or accumulation in fruits when no seeds are produced.

It is a well-known fact that in certain interspecific crosses or even in intergeneric crosses, the ovary may develop into a fruit without any seeds. According to Yasuda (1935) the pollen tubes bring into the ovary something which stimulates growth. This is undoubtedly auxin (Gustafson, 1937). The auxin brought into the ovary is certainly not sufficient to cause continued growth, and the query has been made as to where this additional growth substance

Table 4. Comparison between auxin concentration in normal and parthenocarpic tomato fruits. Auxin concentration is denoted in terms of indole acetic acid equivalent, and the figures indicate gammas per kilogram fresh weight.

6.5 cm 2.57	7.53	0.73	2.06

comes from. Another variation of the above question has been concerned with the growth of normal parthenocarpic fruits as oranges, lemons, and grapes. Where does the auxin come from that causes them to grow? There is probably no pollination and no development of seeds. In artificial parthenocarpy produced by chemicals, interest has centered around the continuation or non-continuation of growth in a fruit after the initial stimulation. Gustafson (1937, 1938a, 1938b) has reported a number of instances in which the initial growth stopped very soon, whereas at other times a fruit continued to grow until half size and then stopped; in still other fruits growth continued until maturity. What is the cause of this difference in behavior? Is the auxin supplied to the ovary in the form of paste or spray causing all of the growth during the enlargement of the fruit, or does the developing fruit itself supply a part? Gardner and Marth (1937) found that four sprayings produced a larger percentage of setting than

a single spraying. It is not clear whether this means that a greater percentage of flowers on a branch produced fruits or whether a larger number of treated flowers produced fruits. From the sentence following their statement that several treatments are more efficacious than a single one, it seems that they have reference to the whole branch. "In the practical use of these compounds in producing fruit on holly, successive spraying would be necessary in that the blossoms are not all open at one time." Several injections of auxin into ovaries and fruits of tobacco produced no more growth than a single injection, according to Gustafson (1938a). If Gardner and Marth's statement has reference to a cluster of holly flowers as a whole, it would seem that the added auxin merely initiates the growth and that the ovary either produces or obtains from the leaves enough for its continued growth and that if this source is not sufficient for the needs, the fruit stops growing.

To obtain information on this point, tomato fruits were produced parthenocarpically by means of phenylacetic acid. Phenylacetic acid, as mentioned before, has only a very slight influence on the Avena test. The auxin determination was made in the usual way. Table 3 shows one of these experiments, and in table 4 are found two more determinations on such fruits.

Parthenocarpic fruits produced by naphthalene acetic and indole butyric acids were also used, and table 5 gives the results for peppers. These fruits were grown in the greenhouse, during the spring and early summer.

According to Went and Thimann (1937), indole butyric and naphthalene acetic acids produce slight curvatures in Avena coleoptiles so that we have no information about the naturally occurring auxin in these experiments, but they definitely demonstrate that there are growth promoting substances in the growing fruits to which the Avena is sensitive; whether these are the substances added at the time of flowering or natural growth hormones, we do not know. The concentration of this active substance is lower than in normal fruits, however.

In the experiments with fruits produced by phenylacetic acid there is no doubt that parthenocarpic tomatoes contain naturally occurring auxin. If auxin occurs in tomatoes, one would expect it to be present also in other fruits. Whether this auxin is produced in the fruit or conducted into it from other

Table 5. Comparison between auxin content in normal and parthenocarpic peppers. Amount of material used is denoted in grams inside the brackets. Auxin concentration is denoted in terms of indole acetic acid equivalents, and the figures indicate gammas per kilogram of fresh material.

0.53 (15.0) 0.80 (16.6)	0.1 (100.0)	0.25 (49.5)	0.18 (51.0)

sources, we do not know, and it need be of no concern. That it is there is the main point.

It then seems very likely that in some fruits there is a quantity of auxin sufficient for the needs of continued growth, after growth has once been initiated, even though no seeds are produced, while in others the amount is too low for the needs of a continued growth, and development ceases after some time. In varieties where mature parthenocarpic fruits have never been obtained, it is likely that the naturally occurring auxin content is always too low to sustain growth after the artificial supply has been depleted, and the only way such fruits can be made to grow and mature is by continuously supplying them somehow with auxin as do the seeds in non-parthenocarpic fruits, but we have not yet discovered a method of successfully doing this.

In normal fruits in which pollination and fertilization are necessary we can consider it a reasonable hypothesis that the initiation of growth of the ovary into a fruit results from the auxin brought into it by the pollen tubes. If this is true, then one might expect that right after pollination the auxin content should be higher than just before. Meyer reports that just after fertilization, which might have reference to pollination, the auxin concentration in the female flowers of Cucurbita Pepo, Cucumis sativus, and Helianthus annuus was much higher than just before fertilization, and he also makes the general statement that there is less growth hormone in female flowers before fertilization than afterwards. In the present investigation there is little if any evidence that there is more auxin after pollination than before. In fact, it would be very difficult to get such information when much material is needed for extraction. Even if it could not actually be shown that the auxin content was higher after pollination, that is no serious criticism of the hypothesis, because even a little auxin added in the right place, as the ovules, would be sufficient to cause them to grow and set up auxin centers from which auxin might diffuse into the ovary. In a preceding paper (Gustafson, 1939), it was shown that in two-week-old Paper rind and Valencia seeded oranges the auxin content had increased very much over that in the flower stage. After the embryo has commenced growing, auxin in considerable quantity is present in the seed. This auxin undoubtedly diffuses into other parts of the ovary, where growth takes place. Even if seeds are not produced, there is auxin present in the ovary.

Some may hesitate to accept the idea of auxin playing such an important rôle in the growth of fruits. Let these consider that fruits have artificially been started and caused to develop by the addition of auxin. If auxin is able to do this when added from the outside, is there any reason why it should not play an important part under normal conditions? Furthermore, let it also be remembered that the mere pollination without fertilization does sometimes cause fruits to develop, and auxin has been extracted from pollen (Laibach, 1932; Thimann, 1934), and Gustafson (1937) extracted a substance which, when placed on the pistil of a flower, caused it to develop into a fruit. All these experiments show that there is auxin in the pollen and that it may cause growth of fruits.

In spite of these statements it is to be understood that auxin is not considered to be the only factor involved in fruit growth. In a recent publication Went (1938) considers that auxin acts in such a way as to cause other substances which he calls calines to move to the part of the plant where growth takes place. Thus he considers that auxin causes the caulocaline to move to the apex of a stem where it functions in the growth of the stem. The auxin may then be thought of as a master reagent causing other substances to produce growth of one sort or another. If this idea is applied to the growth of fruits, it becomes obvious that auxin causes some other substance or substances to move into the ovary of a flower and there cause growth to take place. It is not necessary at the present time to have a name for such a hypothetical substance, but by analogy it

### SUMMARY

would be carpocaline, if different from other forma-

The auxin content of ovules and developing seeds is much greater than that of other parts of fruits, and it is considered possible, even though not yet proved, that they produce auxin.

Auxin other than that added artificially is found in fruits that have been produced by treating the flower by phenylacetic acid.

The probable rôle of auxin in the growth of parthenocarpic and non-parthenocarpic fruit is discussed.

### OBSERVATIONS ON THE GENUS PSEUDOLPIDIUM 1

### D. A. McLarty

Following the early observations of Nägeli (1846), several workers, including Cienkowski (1855), Braun (1855), and Pringsheim (1860), reported the presence of various bodies in swollen filaments of water molds; but little intense work was done on them until Cornu (1872) published the results of his studies. He recognized these bodies to be parasites and described several species, in three of which he observed spiny, thick walled resting spores with one or more smooth or slightly echinulated, thin-walled, empty cells attached to them. Cornu considered these spores to have arisen from a fusion of a smaller male thallus with a larger female one and interpreted the empty cells as the antheridia. Using this sexual spore character as the diagnostic feature, Cornu thus established the genus Olpidiopsis for these small, intramatrical parasites.

Later Fischer (1880), studying what he thought to be Cornu's type species O. Saprolegniae, failed to find resting spores with attached antheridial cells and came to doubt Cornu's earlier observations. In 1882 he rejected the "adjacent cell character" and restricted the genus Olpidiopsis to forms which possessed asexual resting spores. Subsequent studies, however, convinced Fischer that his earlier work was incorrect, and in 1892 he confirmed the observations of Cornu and reinstated the genus Olpidiopsis to its original status. At the same time, he established the genus Pseudolpidium to include Olpidiopsis-like species which produce resting spores without adjacent cells. Of the six species which Fischer recognized, only two are tenable, inasmuch as he did not observe the resting spores of four of them. In P. Saprolegniae he described smooth, flatspherical to ellipsoidal zoosporangia (fig. 5, 6) and spiny resting spores of similar size and shape (fig. 9). In P. fusiforme Fischer described smooth, long ellipsoidal to cylindrical zoosporangia associated with similar long, spiny resting spores (fig. 2).

Butler (1907), studying various other species of Pseudolpidium, has not supported Fischer with ref-

1 Received for publication January 14, 1939.

The writer wishes to express appreciation and thanks to Prof. H. B. Berdan, of the University of Western Ontario, for the culture from which this study was made, and to Prof. J. S. Karling, under whose direction this investigation has been carried on, for his help and criticism.

erence to this striking similarity between the zoosporangia and resting-spores but in all cases describes and figures spherical, definitely thick-walled, spiny resting spores which differ from the *Olpidiopsis* type of spore only in the absence of the adjacent cells.

In swollen filaments of Achlya secured in November, 1937, conspicuous, cylindrical, smooth sporangia (fig. 10) were observed together with long, spiny sporangia (fig. 11) as described by Fischer for P. fusiforme. In the same culture smooth, ellipsoidal zoosporangia (fig. 14) were present as well as spiny sporangia of the same size and shape (fig. 15), which have been described by Fischer for P. Saprolegniae. Dependent apparently upon conditions of growth, zoosporangia were found to vary greatly in size and shape, and in any culture a complete series from spherical to cylindrical could be observed. Spiny sporangia showed similar variation in size and shape, and the degree of spininess was found to vary from slight echinulations to heavy bristles. These bristly bodies showed no tendency to rest but liberated zoospores readily, thereby proving themselves to be nothing more than zoosporangia which,

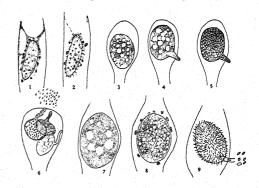

Fig. 1-9 were copied from plates given by Fischer and Pringsheim.—Fig. 1-2. Stages in the development of the resting-spore of Pseudolpidium fusiforme (127×, after Fischer).—Fig. 3-5. Stages in the development of the zoosporangium of Pseudolpidium Saprolegniae (127×, after Fischer).—Fig. 6. Zoosporangia of Pseudolpidium Saprolegniae (87×, after Pringsheim).—Fig. 7-9. Stages in the development of the resting-spore of Pseudolpidium Saprolegniae (117×, after Fischer).

probably in response to some condition of the host protoplasm, become covered to a greater or lesser degree with bristles. For the sake of clarity it seems advisable to refer to these as bristles in contrast to the heavy, broad-based spines found on the wall of true resting spores. Spherical, thick-walled, asexual resting spores (fig. 17), of the type described by Butler for various species of *Pseudolpidium*, were present as well as spores of the *Olpidiopsis* type (fig. 16).

Monospore cultures were established from zoospores isolated from all types of sporangia present in the infected Achlya. Regardless of the type of sporangium from which the spore was taken, however, the monospore cultures were all precisely the same. All the sporangial types present in the original culture were represented in the monospore cultures along with resting spores formed with or without adjacent cells. In consecutive culture generations the ratio of sexual to asexual spores, as indicated by the presence or absence of adjacent cells, varied considerably, although the asexual spores remained always the more numerous.

Inasmuch as the bodies which Fischer described as resting spores are merely zoosporangia bearing bristles, Fischer's description of the genus Pseudolpidium must be revised to include zoosporangia of this type as well as smooth walled sporangia. In view of Butler's work, it seems necessary to maintain the genus Pseudolpidium to include his asexual species. Here again, however, the genus must be revised in relation to the spherical, heavy-walled resting spores. Moreover, monospore cultures indicate that the structures which Fischer described as zoosporangia and resting spores of two species are simply modifications of the zoosporangium of a single organism.

Sexuality, in this form at least, is not well established and definite, but appears to be rather a potentiality the expression of which may possibly be associated with or dependent upon certain obscure cultural conditions. In view of this evidence the nature of the resting spore is not a suitable character upon which to base generic distinctions. Cytological investigations now in progress may serve to explain the nature of sex in these two closely related genera. For the present we may consider this form as a species of *Pseudolpidium* which is predominately asexual but which, under certain conditions, may dis-

play some sexuality. Careful study of the species of Olpidiopsis and Pseudolpidium may reveal that there are many such transitional forms or that all sexuality in this connection is relative.

### MEDULLOSA DISTELICA, A NEW SPECIES OF THE ANGLICA GROUP OF MEDULLOSA <sup>1</sup>

James M. Schopf

MEDULLOSA DISTELICA is the third species of this genus to be discovered in America. Some years ago Thiessen (1920a, 1920b) illustrated a pyritized tristelar Medullosa in connection with his studies of bituminous coal. This form was identified as Medullosa anglica, but after reexamination of Thiessen's specimen, it seems best to class it as a distinct variety. The origin of Thiessen's specimen is unknown beyond the fact that it had been collected on one of the earlier reconnaissance trips in the western coal fields of this country.2 Medullosa noei, the second species, was recently described by Steidtmann (1937). It is from coal balls found in a thin locally mined coal a few miles east of the town of Calhoun, Richland County, southeastern Illinois. The limestone above the coal at this locality has been described (as LaSalle) by Newton and Weller (1937) and is placed at about the middle of the Mcleansboro formation. This formation is considered roughly equivalent to the Conemaugh of eastern United States. In Richland County the Herrin (No. 6) coal at the base of the McLeansboro is about 800 feet below the Calhoun coal.3 The third species, here described as Medullosa distelica, is from coal balls out of the upper part of the Herrin (No. 6) coal bed (Cady, 1936) in the mine of the Clarkson Coal and Mining Co. at Nashville, Washington County, Illinois. The Nashville coal balls were discovered in April, 1935, by G. H. Cady, L. C. McCabe, and C. G. Ball of the Illinois Survey. These calcareous concretions have provided a variety of fossil plant material representative of that which contributed to the formation of the upper part of this coal bed. New plants, such as the one treated in this paper, will be described from time to time independent of studies on the botanical constitution of coal, since such fossils have special botanical and stratigraphic significance.

Medullosa distelica sp. nov.—Stem oval, of medium size, measuring  $ca.8 \times 4$  cm. when slightly compressed. Two highly asymmetric protostelic cylinders each  $ca.7 \times 18$  mm. in diameter with mixed "pith" occur within the bandlike internal periderm. Secondary wood strongly developed on

<sup>3</sup> Records of the Division of Subsurface Geology, Illinois State Geological Survey.

each stele toward the center of stem, much less developed on external sides of each stele; little or no secondary xylem associated with outgoing leaf traces. Internal periderm 11/2-3 mm. broad and originally probably continuous around the stelar tissues. The periderm band is not broken where the outgoing leaf traces pass through. Three extremely decurrent leaf bases occupy the outer 1-2 cm. of stem. two of which are demarcated internally by a sclerenchyma zone. Internodes long. sclerotic rind is of Myeloxylon landroitii type, 2-4 mm. thick, with its internal boundary not strictly definable. Secretory ducts enclosing "resin rodlets" numerous and commonly associated with sclerotic strands. Leaf trace bundles are chiefly of the typical centripetal collateral type; they are a little more massive when entering the leaf base but soon bifurcate to assume their typical configuration.

The holotype was derived from an approximately spherical coal ball. The stem was situated somewhat excentrically within the nodule and exposed in slightly oblique section by the first exploratory cut. About 5 inches of the stem was available for

study

Figures 1 and 2, plate 1, are taken from opposite extremities about 4 inches apart, where in each case the specimen is fairly complete. Figure 1a is a tracing taken from the photograph in 1b. No leaf traces are indicated in this or other drawings. The stelar structures, similar to those shown in plate 1, figure 1a, have been drawn at successive levels approximately an inch apart and are shown in their normal succession in text figure 1c, d, and e; figure 2, plate 1, is thus subjacent to text figure 1e.

The phyllotaxy merits no special comment at this time except to note that the same leaf bases are present throughout, and thus a long internode is indicated. Internal sclerenchyma setting off two of the leaf bases is present, making it more like Medullosa centrofilis (De Fraine, 1914) than M.

anglica in this respect.

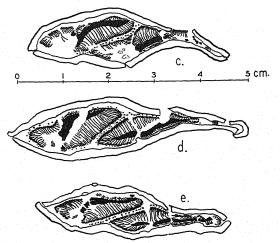

One of the distinct features of this species is the extreme asymmetry of the xylem cylinders. By asymmetry is meant deviation (in this case bilateral) from the radial development common to most steles of vascular plants. In Medullosa distelica asymmetric stelar growth is most prominently displayed by the secondary wood which is narrow on the external side of the individual stele and much thicker internally. Medullosa anglica (Scott, 1899) shows similar asymmetry of the steles but in a lesser degree; thus far this feature has attracted little attention. In M. anglica the asymmetry of growth might be explained, at least in part, as due to depletion of the peripheral wood by outgoing leaf traces. Since the leaf traces are considerably less massive in M. distelica than in M. anglica, they are probably not directly responsible for the more extreme thinning of external secondary wood in the Nashville specimen. The contrasting development of internal and external secondary wood  $(x^2)$  at the end of the steles is shown in figure 3, plate 2. Flattening of the two steles in M. distelica, as shown in text figure 1c, d, and e, may be due to the mechanical pressure developed by growth of one stele against the other.

The internal zone of secondary wood is relatively thick, up to about 5 mm. The normal tracheids are large in transverse section (150  $\mu$  or more in diameter) and slightly broader in a radial They are aligned in rows of one, two, direction. or three cells' width between rays. The rows more than one cell in width generally show the alternating arrangement of tracheids characteristic of Medullosa wood (fig. 3). This is probably indicative of cambial activity somewhat different from that found in most modern plants. The tracheids are covered with characteristic multiseriate pits on their radial and obliquely tangential walls (fig. 7); few pits are present on the squarely tangential faces. The rays are numerous (4 or 5 per mm. as measured tangentially) and narrow. They appear as parenchymatous continuations from the mixed "pith," generally several cells wide when first entering the secondary tissue, but for the most part they soon diminish to one or two cells in thickness. In tangential section the rays are fusiform and, although their height is difficult to determine from this specimen, some apparently extend vertically for as much as a centimeter. The last formed cells of each xylem row decrease in size approaching the margins, as shown in figure 3, until the last formed elements in this area are less than  $\frac{1}{4}$  the size of those forming the normal secondary wood. In this last formed (incompletely differentiated?) part of the secondary cylinder the rays are again a little wider.

Neither phloem nor pericycle is preserved and several Stigmarian rootlets have invaded the area between xylem and periderm. The space between the two steles contains some dark disintegrated material and a row of black "resin rodlets" similar in character to those of the petioles, except that they are considerably smaller. These rodlets are indicated by the rows of dots between the steles in text figure 1. Little except the presence of these secretory elements can be determined of the tissues immediately outside the secondary wood.

The primary wood (mixed "pith") is poorly preserved except for clusters of large primary tracheids (plate 2, fig. 3,  $x^1$ ). In some places the intervening parenchyma is present, but in many places Stigmarian rootlets have also invaded this region. Thus far position of the protoxylem has not been assuredly identified. However, since the internal cells of the secondary xylem are well preserved in part and show no protoxylem directly adjacent, it seems likely that M. distelica developed mesarch protoxylem.

The species is characterized by development of a very narrow zone of secondary wood on the external side of each stele as shown in plate 2, figure 3 (outer  $x^2$ ). In places the primary wood seems to have been in direct contact with the pericycle; lat-

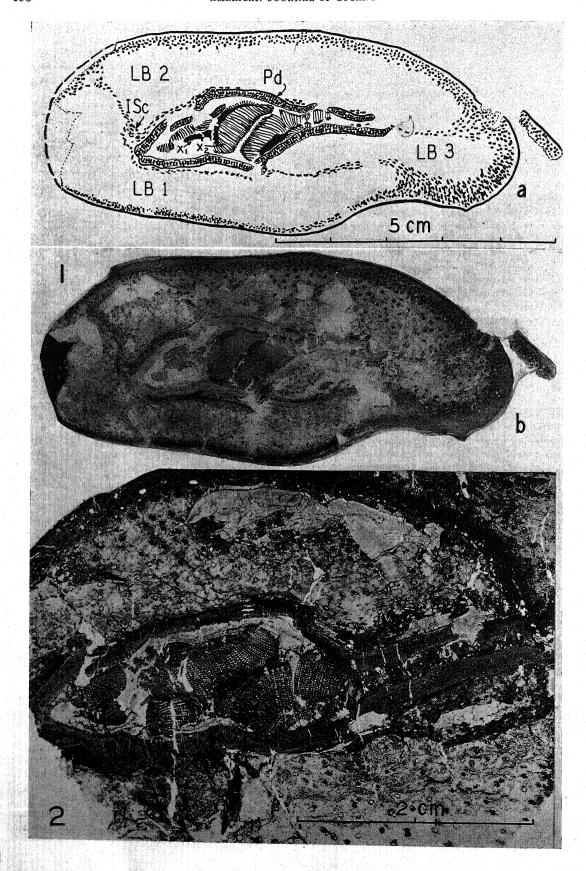

Text fig. 1. Medullosa distelica. Diagrammatic tracings of the vascular tissues and internal periderm in sections spaced about 1 inch apart. Primary xylem, black; secondary xylem, lined. Sections are in their natural order, c below the section shown in plate 1, fig. 1; e above the section shown in plate 1, fig. 2. The tissues are considerably broken in certain areas due to intrusion of foreign roots and small veins of secondary calcite. c from 49C (B2), d from 49C (T1), e from 49B1a (B1), Illinois State Geological Survey collection.

erally from these spots the secondary tracheids increase in number, particularly toward the thick inner wood.

Outside the steles there are a few isolated bundles of primary tracheids which apparently went to supply the petioles. Although the structure of these is not very satisfactorily shown, it seems certain that few or no secondary tracheids accompanied the leaf traces away from the steles. This is a character in considerable contrast to Medullosa anglica where radially oriented secondary xylem continues around the outgoing leaf trace for several centimeters.

In a few instances somewhat dislocated leaf trace bundles were observed completely surrounded by the periderm or secondary cortex (plate 3, fig. 13, VB). The bundles, nevertheless, may have functioned normally. Although De Fraine (1914) and more recently Steidtmann<sup>4</sup> have pointed out that the internal periderm was probably not an impervious suberized cork layer (morphologically it resembles corky tissue) (fig. 13, Pd), the bundles traversing it constitute the most likely channels for conduction. In Medullosa anglica the leaf traces accompanied by secondary wood were apparently too large to be completely enveloped by the narrow periderm, and hence they form a gap in the periderm sheath where

4 Unpublished manuscript.

they pass through it to the leaf base. Although periderm surrounds the smaller vascular traces for an interval in M. distelica, there is no reason to suppose that the course of conduction was different from that in M. anglica.

Since Medullosan material is not abundant in the Nashville coal balls, the Myeloxylon petioles found there most probably all belong to Medullosa distelica. Traverses measured across a representative series of these concretions show that various tissues of Medullosan origin are present in not more than  $2\frac{1}{2}$  per cent of the area. In the other species of Medullosa the sclerenchymatous rind (or hypoderm) of both stems and petioles has been sufficiently similar in character to indicate rather conclusively the affinity of associated but isolated petioles. If the Nashville stem and associated but unattached petioles belong together, it is apparent that the rind varies somewhat more from stem to petiole on this plant than is reported for other species. (Compare fig. 9 and 12, plate 3, with 1b and 2, plate 1.) In the leaf bases attached to the stem the sclerenchymatous strands are small and numerous, similar to those of Myeloxylon landroitii described by Renault (1876). The strands in isolated Nashville petioles on the other hand tend to be a little larger and more radially elongated. In some sections they seem more like the M. radiata type of Renault.

The sector of a petiole illustrated in plate 3, figure 9, shows the leaf trace bundles to good advantage. It seems likely that the part of the petiole illustrated here was basal and had been broken from a stem. It agrees with the complete petiolar bases attached to the type specimen in width, and one side of the rind was missing as though it had been broken from its decurrent attachment to the stem. Furthermore, the bundles are seen in stages of bifurcation just as in the type specimen. A double bundle is shown at the lower right in figure 9 (DB). The pairing of recently bifurcated bundles more centrally placed is also shown.

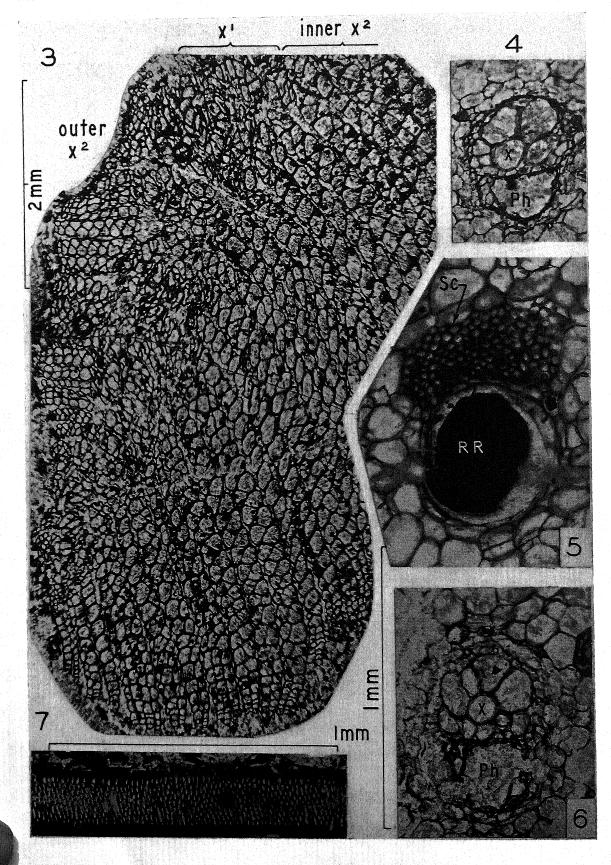

The collateral leaf trace bundles of M. distelica are shown in plate 2, figures 4 and 6. Cells of the phloem area (Ph) are almost entirely disintegrated, but the cavity which they formerly occupied is preserved without distortion. The xylem (x) consists of a few tracheids showing a gradation in size away from the small protoxylar tracheids placed next to the phloem. In M. distelica the bundle sheath is quite narrow, and the cell walls are not strongly thickened. The bundle sheath in figure 6 has become disintegrated, while the xylem tracheids are still adequately preserved. This may be indicative

of the comparative degree of lignification in the two

The secretory canals of the petioles are large and numerous (plate 3, fig. 9, RC). In the central part of the leaf base they generally lack any sclerotic accompaniment, but toward the sclerotic rind a strand of thick walled sclerenchyma is generally associated with them. The canals are also shown in plate 1, figure 2, and one accompanied by a small patch of sclerenchyma is shown at higher magnification on plate 2, figure 5. An epithelial layer is present. The contents of these canals have long been objects of interest to coal petrographers. Isolated from coal they are rod like in form and frequently preserve external imprints of the epithelial cells of the canals. Chemically they are very inert since they withstand drastic chemical oxidation with no observable change and are most like fusain in this respect. They have been called "resin rodlets," although it has long been realized that their resinous nature is inadequately proved. The name nevertheless serves to characterize them rather well, since they are essentially similar to resin in their mode of occurrence within the plant. A closer comparison of the secretory ducts might be drawn from the mucilage canals of certain Cycads, but it is hard to conceive of Cycadean mucilage assuming such a hard imperishable form. These resin rodlets are essentially opaque even in extremely thin sections, which of course makes their simple resinous nature more doubtful. The presence of these bodies in their typical form within well preserved Medullosan petioles and stems may be taken as evidence that the rodlets lost their fluid consistency very early, perhaps even before death of the plant. The process responsible for their present condition is one of considerable interest to students of coal as well as to paleobotanists, since it has bearing on the origin of fusain or mineral charcoal in coal. If the rodlets were even slightly volatile prior to coalification, the presence of characteristic and typical rodlets in both fusanized and unfusanized plant tissues would seem to rule out prehistoric forest fires as the agent responsible for this coal constituent. A volatile plant secretion presumable would have been distilled out by the heat. The rodlet (RR) shown in figure 5 has been slightly distorted by a cross fracture subsequent to the original mineralization.

Figure 12 shows two isolated petioles which may represent the main rachides further removed from their stem. One of these shows two secondary branches (b) being given off at about the the same

Plate 1. Fig. 1-2.—Fig. 1a. Medullosa distelica, transverse section of holotype. Interpretative tracing from photograph shown in figure 1b. Leaf trace bundles not indicated.—Fig. 1b. Medullosa distelica, transverse section of holotype, original of figure 1a. From 49D3b (T1). (This and other similar combinations of characters indicate the source of the material illustrated among the coal ball collections of the Illinois Survey. By use of this system the original location of the many nitrocellulose films and thin sections which were prepared may be rather accurately defined.)—Fig. 2. Medullosa distelica, transverse section of holotype near one extremity. The stele at the left is somewhat unusual and may be in process of division. From 49A (T4). Specimens in the Illinois State Geological Survey collections at Urbana.

level. It would seem from this and other similar occurrences that branching of the leaf axis was monopodial and opposite. No evidence of dichotomy has been observed, although Seward (1917, p. 87) has suggested that this method of branching was more common in *Medullosa* and other pteridosperms than in the true ferns. A secondary petiole is shown at intermediate magnification in plate 3, figure 11; the two bays of parenchyma invading the sclerotic rind at b and b', opposite one another and a little above the center, indicate the position of tertiary petiolets. An isolated petiole of this last order is shown in figure 10 at the same magnification as in figure 9.

Alethopteris-like leaflets are closely associated with tertiary petioles. The pinnules are 21/2-3 mm. broad, about half as large as those associated with M. noei. Between veinlets the tissues include the following: upper epidermis of small cells, hypodermis (usually much better preserved than the epidermis) of large cells with secretory contents above veinlets, and chlorenchyma of medium sized cells slightly elongated at right angles to the plane of the blade. A large unobstructed air space separates the lower epidermis (with cells somewhat larger than those of the upper epidermis) from the chlorenchymatous tissue. Chlorenchyma cells are one or two layers deep above the air space but more numerous around the border tissue of veinlets. The mid-vein alone has a band of sclerenchyma around its convex lower margin. The margins of pinnules are strongly reflexed; ecologically the leaves seem to resemble those of modern swamp xerophytes.

No adventive roots are present on the stem described here, but several isolated tetrarch Medullosan roots have been found in association. The xvlem of these Nashville roots is satisfactorily preserved (plate 3, fig. 8), but external tissues are not well displayed. Psaronius and Stigmarian rootlets generally have penetrated and distorted the softer outer tissues. The primary xylem in Nashville Medullosa roots is nearly quadrangular in cross section; the sides are only slightly extended beyond the squarish body of primary wood. The roots of Medullosa noei Steidtmann (1937) and the Medullosan roots discussed by Hoskins (1931) seem distinguishable from the Nashville roots, since the sides of the primary wood in their figures are shown to be considerably more concave in transverse sections and the protoxylem points are further extended.

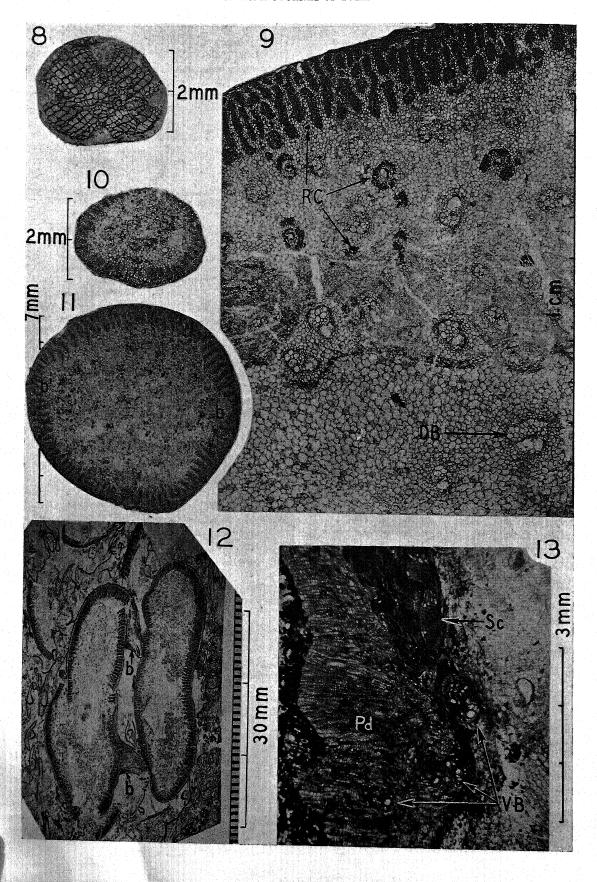

COMPARISON WITH OTHER SPECIES. 5—M. distelica is more closely related to M. anglica than to M. noei. The large size of the latter indicates an approach toward the specialization which characterized the Medullosaceae of the Permian. M. distelica is presumably intermediate in age between M. anglica and M. noei and might be expected to show intermediate characters. On the contrary, the characteristics of M. distelica are divergent in many particulars from those which might have been predicted from these previously known species, and any conception of a simple phylogenetic series may as well be discarded for the present. However a few points may be selected for comparison which seem phylogenetically significant or promising in the sense of a "Merkmals-phylogenie" (Zimmermann, 1930, p. 427).

The asymmetric development of secondary wood in Medullosa distelica may be considered first, since this feature seems to be common in the older members of the genus and most extremely exemplified by the Nashville stem. In Medullosa anglica the secondary wood on external sides of the three steles is apparently less than half the thickness of the internal secondary wood (Scott, 1899, pl. 5, phot. 1; pl. 6, phot. 5). Medullosa centrofilis De Fraine (1914) shows about the same degree of asymmetry and M. pusilla Scott (1914, pl. 13, fig. 3), although considerably smaller than the other species and hence not so subject to limiting factors of size, still shows the same asymmetric features to a significant degree. Tracings from published photographs of these species are shown in text figure 3. The type of secondary wood development has not received much attention, because it is obviously sensitive to local factors of the environment. This consideration, however, does not carry equal weight in the case of Medullosa. The fact that the four distinct older species all show a similar variation indicates that for this group the feature is phylogenetically significant. The argument possesses additional weight from the consideration that the thicker secondary wood centrally placed could not possess much survival value as a mechanical support to the plant.

Medullosa solmsii, M. stellata, and M. porosa are of Permian age and hence considerably younger

<sup>5</sup> It should be mentioned that the author has had the advantage of consulting not only Dr. Steidtmann's published description of *Medullosa noei* but also his more complete manuscript now on file awaiting publication by the Illinois Survey and dealing with this very interesting species. The extensive bibliography given there has facilitated the work in preparing the present paper, and Steidtmann's detailed description has aided in making a comparison between *Medullosa noei* and *M. distelica*.

than the three English species or the American forms. The three Permian species mentioned were arboreal in structure in marked contrast to the others mentioned. This was made possible by development of a relatively great thickness of secondary wood on the external side of several steles or of one stele which came to dominate the vascular structure by curving around accessory steles and common ground tissue in the center of the stem. Thus the secondary wood again was developed asymmetrically in the principal stele or steles, but in these cases it was obviously a supporting tissue, and the principal direction of secondary growth was reversed. It is difficult to see how the woody tissue of a polystelic stem could become mechanically competent for the support of a tree by any other course of development. Since the asymmetric features of the older Medullosans were not appreciated, the full significance of arboreal development in the Permian forms also escaped particular notice. It follows, however, if stelar asymmetry is a significant feature among the older species, as it seems to be, and if these Carboniferous Medullosans are ancestral to the Permian forms, even if only in a broad sense, that the asymmetric stelar development is also of definitive significance in the latter group.

To facilitate discussion and reference to these contrasting types of secondary growth, the following terms may be useful. The types of asymmetric growth found in the older species of *Medullosa* in which the internally oriented secondary wood becomes significantly thicker, may be termed endocentric (see text fig. 2a). The contrasting type in which the externally oriented secondary wood attains the greater prominence may be termed exocentric (see text fig. 2b). It must be understood, of course, that these terms have the center of the stems (as distinct from the centers of the steles) as a reference point.

Medullosa noei and M. leuckarti seem to show about equal development of secondary wood on the internal and external sides of the principal steles, although the former is much more regular in its stelar development than the latter. If the exocentric or endocentric growth of secondary wood is accepted as a character of importance within the genus, then we must think of M. noei and M. leu-

ckarti as intermediate in the series. The geologic ages of these two forms also seems to lend support to this interpretation. Thus, on the basis of the type of secondary growth we seem to have an illustration of evolution from plants with inefficient stelar supporting tissues to plants of considerable efficience in this one particular within the basic

limitations imposed by a less flexible polystelic structural plan.

Medullosa distelica provides no significant evidence concerning the origin of polystely in this group. The presence of only two instead of three or more steles is certainly a valid species character, but it is not clear whether this is a step toward simplification of the polystelar condition or an ancient hold-over from a primitive less complex stelar constitution. In the past several authors have suggested a possible alliance between the Cladoxyleae with many "steles" (of endocentric configuration) and the Medullosaceae. However, Bertrand (1935) has shown conclusively that Cladoxylon is the stem which bears certain Zygopterid phyllophores (Clepsydropsis) so that relation to the Cycadofilicales is no longer plausible. De Fraine (1912) has suggested that the monostelic Sutcliffia more nearly approximates the primitive stelar form of the Medullosaceae. This still seems

Plate 3. Fig. 8-13.—Fig. 8. Medullosa rootlet, transverse section. The nearly square outline of primary xylem is clearly shown. From 113-3 (T4).—Fig. 9. Myeloxylon petiole associated with Medullosa distelica. The sclerotic strands of the rind are more radially elongated in this sector than in the holotype of M. distelica. Secretory canals (RC) are numerous both with and without sclerenchyma strands in conjunction. Black contents of canals are "resin rodlets." Paired leaf trace bundles occur along the horizontal mid-line of the photographs, and a double bundle (DT) in course of division is shown lower at the right. From 44A3.—Fig. 10. Tertiary petiole of Myeloxylon. The hypodermal sclerenchyma has assumed a dorsiventral arrangement. Magnification is the same as in figure 9. From 44c.—Fig. 11. Secondary Myeloxylon petiole. The parenchymatous bays in the marginal sclerenchyma at b and b' represent points at which tertiary petioles arise. From 64B2b (B1).—Fig. 12. Myeloxylon petioles which probably represent main rachides further removed from their stem than the sector shown in fig. 9. The small black specks within the marginal sclerenchyma are nearly all resin rodlets. The petiole at the left is giving off two secondary petioles (b). Many transverse and oblique sections of Lepidophyllum sp. are also present. From 62D1 (T1).—Fig. 13. Medullosa distelica, sector from the specimen illustrated in figure 2. Leaf traces (VB) have been enveloped by the periderm (Pd) and somewhat disarranged. Internal sclerenchyma strands (Sc) of an adjacent leaf base are shown close outside the periderm in the upper part of the figure. From 49A (T4). Specimens in the Illinois State Geological Survey collections at Urbana.

to be an acceptable interpretation. Nevertheless, in consonance with the next point to be discussed, it seems more tenable to consider the distelar condition in the new Nashville Medullosa as reduced from a more polystelar type rather than as directly derived from an ancestry reminiscent of Sutcliffia. It is also apparent that the extreme endocentric asymmetry found in M. distelica is not a primitive feature. For these reasons, in spite of the apparent simplicity in stelar construction, M. distelica should be considered as a more advanced form than M. anglica.

The amount of secondary wood accompanying leaf traces as they leave the stele may be sig-This is suggested by the organization found in Sutcliffia which on other grounds may be considered as primitive within the family. The leaf traces in mature stems of Sutcliffia are qualitatively similar to the central cylinder and are poorly differentiated from it even to the point of rejoining. For convenience they have been termed "meristeles," but the small leaf trace bundles are produced from them according to De Fraine (1912), and because of this they are interpreted as foliar rather than as essentially cauline structures. They possess a considerable development of secondary wood the same as the central cylinder along this "meristelar" portion. Medullosa anglica develops a significant amount of secondary wood radially around the main leaf traces for several centimeters of their proximal extent before they break into smaller collateral bundles. None of the other species of Medullosa are known to possess secondary tracheids along leaf traces, and except for this feature the leaf supply of M. distelica seems to have been quite similar to that of M. anglica. Incomplete as this information is, it may indicate that the differentiation between the megaphyllous leaf and stem was still in progress during evolution of the older members of this family.

The position of the protoxylem may prove to be useful in comparing members of the Medullosaceae, although definite information is not available for several of the species. Sutcliffia is clearly exarch. Medullosa centrofilis is exarch or slightly mesarch, M. anglica is mesarch, and M. distelica is probably mesarch, too. M. noei was not determinable for this characteristic in Steidtmann's material, but from better preserved specimens which the author has examined it is seen to possess protoxylem centrally located in some of the tracheid nests of the primary wood, a definitely mesarch condition. There thus seems to be a tendency for the protoxylem to become progressively less associated with initiation of secondary growth.

### THE ANGLICA GROUP OF MEDULLOSA

Weber and Sterzel's "Beitrage" (1896) approaches closest to a monographic treatment of members of the Medullosaceae. Their studies have dominated the taxonomy of the group in recent years,

although the species they dealt with are chiefly of Permian age. Their contribution is confined in the main to four species; M. porosa (which probably is to be considered the genotype, since it seems to have been the first described), M. stellata, M. solmsi, and M. leuckarti. Weber and Sterzel named different growth forms of the first three of these, based chiefly on the amount of secondary wood. The different forms were grouped under their respective specific designations, each as a "Formenkreis" of one species by Weber and Sterzel. M. leuckarti had no distinct growth forms, although it also was termed a "Formenkreis." Scott gave the most thorough morphologic treatment of any of the species when he described Medullosa anglica (1899) from the Lower Coal Measures of Great Britain; several years later he described Medullosa pusilla (1914) from about the same horizon. When De Fraine (1914) described M. centrofilis (also of Lower Coal Measures age), she suggested that these three older species be grouped as the Medullosa anglica "Formenkreis" or "form-cycle." As a temporary expedient this informal grouping served to point out closer relationships within the genus.

Since the forms described in this paper show many features in common with those included in the M. anglica "form-cycle," it does not seem necessarv now to classify the Anglica group on such a provisional basis. This alliance now includes the three English species and two or more American types which are rather definitely distinguished among themselves, but all present a sharp contrast to the exocentric Permian forms. Weber and Sterzel's "Formenkreis" is apparently a convenient designation for a single somewhat variable fossil plant species, but it is inappropriate for the more extensive assemblage discussed here. It is proposed, therefore, that this older alliance of Medullosa species be set apart with the rank of a subgenus and, since it seems to constitute a natural group, that it be accorded formal taxonomic status. This subgenus may be diagnosed as follows:

Subgenus Anglorota subgen. nov.—Plants small to medium size, some possibly of creeping or climbing habit. Stems relatively weak, supporting tissue notably present in the "hypoderm" of leaf bases and petioles. Polystelic; the few (2-4) steles which dominate the vascular system are approximately equivalent; accessory vascular structures (star rings, etc.) few and relatively inconspicuous or altogether absent. Secondary xylem present but insufficient to function as the chief supporting tissue; characteristically grows thicker on the internal sides of the individual steles (endocentric). Internal periderm present and generally bandlike. Stem completely sheathed by relatively large decurrent petiole bases arranged in a simple spiral phyllotaxy. The name Anglorota is essentially a latinization of anglica cycle-i.e., form-cycle.

Type species: Medullosa anglica Scott (1899). Thiessen's Medullosa is closely allied with M. anglica but it deserves at least varietal distinction.

It is therefore proposed to designate it in honor of the late Reinhardt Thiessen. This specimen has been made available through the courtesy of George Sprunk of the U. S. Bureau of Mines, and the author gratefully acknowledges his kind cooperation. The description may be given as follows:

Medullosa anglica var. thiesseni var. nov.—The specimen consists of a slender columnar segment of stem about 14 cm. long and 20 mm. in diameter. The stelar portions and the innermost cortical tissues are preserved by pyrite and hematite with relatively little crushing or distortion. It is longitudinally ribbed and somewhat triangular. Externally there are no indications of leaf bases leaving the stem, although it may be that these were differentiated further out in the more marginal portion which is not preserved. A continuous narrow periderm band separates the stem into cortical and stelar portions.

The preserved cortical part varies from about 4 to 7 mm. thick outside the periderm. The numerous collateral bundles of the cortex seem to lack any particular orientation. From 34 bundles in one sector (including about half of the stem) 6 are obviously double preparatory to dividing, and 25 are simple; the others are intermediate in con-Nine have the protoxylem directed formation. toward the center of the stem, 10 have the protoxylem directed toward the periphery, and the rest are oriented tangentially with the protoxylem on one side or the other. A narrow sclerenchymatous bundle sheath extends around the xylar side of each bundle. Secretory canals with or without a small crescentic accompaniment of sclerenchyma are numerous, 66 having been counted in the sector mentioned above. Sixteen of these have associated sclerenchyma strands located on the internal side. In none of the sections studied has any definable sclerenchymatous zone in the cortex been observed which might be interpreted as the internal part of a leaf base.

The internal periderm is very narrow, twisted, and continuous, similar to that in *M. centrofilis*. It probably does not exceed 10 cells in thickness at any point. Peculiarly, at several points resin rodlets are completely enveloped by the periderm.

Pericycle and phloem within the periderm band are poorly preserved. In a few areas parenchymatous cells can be observed, so it seems likely that if any fibrous elements had been present in this region that they, too, would be seen. Resin rodlets are very numerous especially in the zone between the periderm and the steles, and a row of them is also present between the woody cylinders. These rodlets are about the same size as those in secretory canals outside the periderm, though a few are smaller.

Three steles are present, which apparently run the length of the specimen without significant change. They are smaller, more compactly spaced,

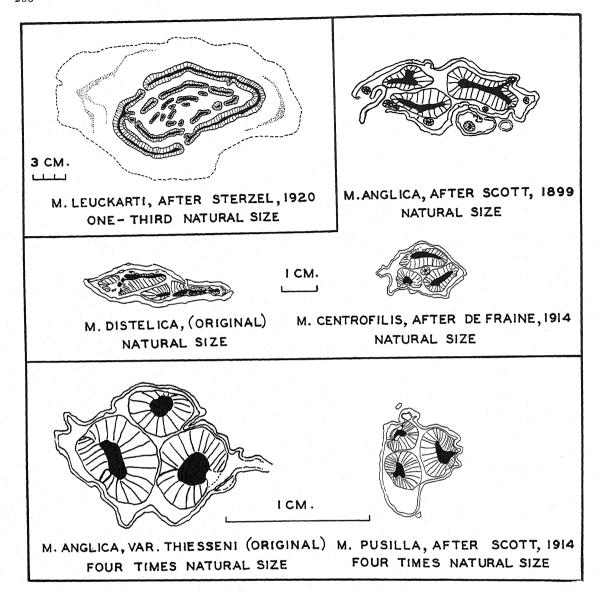

and are much more regular in outline than those in Scott's specimens of M. anglica (text fig. 3). The three cylinders are not the same size, although they are obviously morphological equivalents. They are about 6.6  $\times$  5.2 mm., 6  $\times$  3 mm., and 5  $\times$  3 mm. in diameter, the first measurement in each case being tangential and the last radial to the stem as a whole. This size variation seems consistent throughout the specimen, and it is interesting to note that a similar variation is suggested by cross sections of each of the English forms as well (text fig. 3). The steles of our new variety are asymmetrical (endocentric) as in M. anglica but not quite so extreme. The primary wood follows the same contours as the secondary wood and occupies a little less than a third of each dimension. The primary tracheids seem relatively more numerous than in M. distelica, but precise details are hard to make out, and one cannot be sure of the position of the stelar protoxylem.

The details reported have been observed on relief polished sections of this specimen, since the preserving minerals are opaque and thin sections are of course out of the question. Possibly if more sections were cut, additional details might be added. Thiessen's original illustrations (1920a, 1920b) may be referred to for further elucidation of this variety.

The facts presented seem sufficient to distinguish Thiessen's specimen from M. anglica. If comparable material is discovered in the future at a known horizon, it may even be considered specifically distinct. As matters stand, a varietal name seems sufficient as an adequate means of reference. Medullosa anglica var. thiesseni is significant, since it provides indisputable evidence linking the Anglorota species of America with those known only from Europe.

The other species included in this subgenus are M. pusilla Scott (1914), M. centrofilis De Fraine (1914), M. distelica Schopf described on a previous page, and possibly M. noei Steidtmann (1937). Scott (1923, p. 186) mentions sections in the Renault collection at Paris bearing the name "Heterangium geriense" which he says is a Medullosa belonging to the Anglica group. He suggests that "this species may bear the name Medullosa geriensis," but so far as the author is aware, it is still undescribed. Until some one describes it, "M. geriensis" must be treated as a nomen nudum. However, the sections referred to are reported to come from "the upper coal measures of the Ride de Gier, near St. Etienne," and consequently this form may be geologically the youngest of the Anglorotae.

Features of stelar form and arrangement of Anglorota species are shown by reasonably accurate line tracings in text figure 3. Medullosa noei is larger than any of these and differs in several other particulars. It may be desirable to place M. noei and M. leuckarti together somewhat separate from the rest of the genus, but this must await further study. No tracing of M. noei is given, because no very ex-

Text fig. 3. Stelar systems of Anglorota Medullosans and of Medullosa leuckarti. Primary wood area blacked in; secondary wood lined, lines follow the rows of secondary tracheids. Outer band in each (except M. leuckarti) represents internal periderm.

cellent entire stems are available. However, M. leuckarti is shown for comparison, although it is unquestionably more advanced than M. noei or any of the older forms.

### SUMMARY

Medullosa distelica sp. nov. and petioles, leaflets, and roots associated with it have been described. The stem possesses two highly asymmetric (endocentric) steles. The associated petioles possess a somewhat different type of sclerotic rind than the stem, although they are probably derived from the same species. The roots seem distinguishable from those known from other species of Medullosa and

probably were similarly adventive, although none were found in connection. A few points—viz., the asymmetrical growth of the steles, the leaf trace accompaniment of secondary wood, and the location of the protoxylem in the stem—have been compared with other species. It is pointed out that the type of secondary wood formation (endocentric or exocentric) may be significant within this group for taxonomic purposes. Although M. distelica is simpler in its gross stelar anatomy than M. anglica, this condition is regarded as derived rather than primitive.

The Medullosa "form-cycles" have been discussed briefly. The older species, which include the M. anglica "form-cycle" and American forms, are

considered sufficiently distinct from the rest of the genus to be recognized as a subgeneric group designated as Anglorota. A specimen illustrated earlier by Reinhardt Thiessen shows sufficient agreement with M. anglica to be described as a variety of that

species and indicates best how closely American and European forms are related.

### POLLINATION AND ITS INFLUENCES ON THE BEHAVIOR OF THE PISTILLATE FLOWER IN VALLISNERIA SPIRALIS <sup>1</sup>

### S. B. Kausik

Vallisneria spiralis L., a submerged aquatic belonging to the order Helobiales, has long been known as a classic example of a unique type of pollination first described by Kerner (1891). Twenty years have elapsed since Wylie (1917) studied the American form<sup>2</sup> of this plant and gave a vivid account of the processes involved in the transfer of pollen from the staminate flowers to the stigmatic lobes of the pistillate flowers on the surface of the water. The following account presents the same aspect in the life history based on a form of Vallisneria which grows in India and shows certain essenteria

<sup>1</sup> Received for publication January 10, 1939.

The writer wishes to state that he enjoyed correspondence with Professor Robert B. Wylie, of the State University of Iowa, U. S. A., who has offered helpful suggestions; he wishes also to thank Professor M. A. Sampatheumaran, of the University of Mysore, Bangalore, India, for his kindness throughout the progress of this study and for helpful criticism at various times.

<sup>2</sup> In discussing the diagnostic character of the American form of Vallisneria, Fernald (1918) states that treated as a species it is V. americana Michaux, or as a variety it would be V. spiralis, var. americana (Michx.) Torr.

tial departures from the earlier accounts by Kerner and Wylie. This paper also includes a study of the behavior of the pistillate flowers both prior to and after pollination.

The writer recently noticed large patches of Vallisneria spiralis growing in a small lake adjoining the Government Horticultural Gardens, Lal Bagh, Bangalore, India. Many pistillate flowers had reached the surface of the water and were disposed more or less slantingly, exposing their stigmatic lobes and causing slight depressions of the surface of the water. During quieter periods the staminate flowers glided into these depressions and were grouped together in contact with the stigmatic lobes (fig. 1). But with the formation of waves, the clusters of staminate flowers generally drifted away from the pistillate flowers. This observation suggested that there might be departures from the account of pollination by Wylie (1917). Further, the flowers themselves were found to be rather different from his descriptions. Consequently, a detailed study of pollination and also of the structure of the flowers was undertaken with plants in natural surroundings as well as in the laboratory.

The staminate flower is about 0.6 mm. across the recurved sepals, which are three in number and of which one is smaller. There are two stamens with slender filaments spreading apart at right angles. Each stamen bears distally, when the anther has dehisced, a mass of large pollen grains. The two masses of pollen grains of a given flower project beyond the margins of the sepals (fig. 2-4) so that the

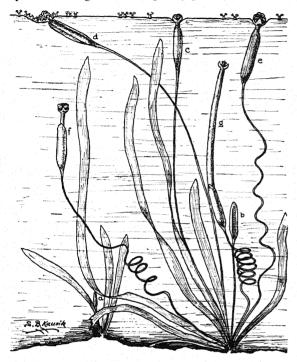

Fig. 1. General drawing of  $Vallisneria\ spiralis\ L.$ , showing a number of freely floating staminate flowers on the surface of water and pistillate flowers in various stages of development, marked a to g.

pollen grains may immediately come in contact with the stigmas of the pistillate flower. In addition to the two stamens, the staminate flower has a rudimentary petal and a small staminodium placed on opposite sides. The staminate flower agrees in many respects with that figured by Kerner (1891), but differs in one respect-namely, that the sepals are unequal, while Kerner's figure shows them as equal and symmetrically disposed. On the other hand, a comparison with the American form studied by Wylie (1917) shows more striking differences in the floral parts. The sepals are of course similar in both. but the pointed hairs described by Wylie as occurring at the base of the stamens are absent. The most important difference, however, is that the stamens, instead of being close together and upraised in the center of the flower, forming a single mass of pollen grains, are divergent with distinct pollen masses.

There are also differences in the structure and development of the sporangia themselves. Rangasamy

(1934) points out that each anther in Vallisneria (available locally) has usually four sporangia which are derived from independent archesporial masses, but suggests that there might be slight variations. On the other hand, Witmer (1937), in a recent study of the American form, states that each anther has normally only two sporangia and that these are formed from a common archesporium later becoming separate as growth in the stamens proceeds.

The pistillate flower also shows important differences, in size as well as in structure, when compared with that in the American plant. It has a slender inferior ovary measuring about 12 to 14 mm. in length at the time of pollination (fig. 6), while Wylie states that it is about 20 to 25 mm. in the American form. The spathe invests the ovary almost up to the base of the spreading sepals, as stated by Wylie, and later forms in the developing fruit only a partial basal investment. On the other hand, the figure by Kerner (1891) shows that the spathe leaves a considerable portion of the ovary below the sepals quite naked even at the time of pollination. Three rudimentary petals are found inside the sepals and attached at the base of the style. No staminodia are seen, but these are said to be present in the American form by both Wylie (1917) and Witmer (1937). There are three stigmas, each of which is bifid with two leaf-like fleshy expansions curling slightly outside and between the sepals to expose the inner surfaces, which are densely clothed with stigmatic hairs (fig. 7). Wylie reports that the bifid stigmas are sharply coiled in the American form when the flowers are fully open and that these coils protrude between and outside the sepals. This disposition of the stigmas in the American form favors contact between the stigmatic lobes and the pollen masses. In this connection it is of interest to note that Professor Wylie, in a recent personal communication, writes: "I am inclined to suggest that while the American Vallisneria does not have the stamens separated, this possible handicap is more than compensated for by the extensive stigmas which are coiled and protrude between and outside the sepals. assuming the recognition you have given to the depression of the surface film. They may possibly be as fully exposed to pollen contact as in your form in which as you say the stigmas are curled outside the sepals."

It is thus seen that the two forms are structurally very different in their flowers. While the pistillate flower in the Indian form is only half as long as that in the American form, the staminate flowers do not appreciably differ in size, being less than a millimeter across in either. The size relationship then, between the staminate and the pistillate flowers in the Indian form, is very different from that in the American form; this disparity is perhaps correlated with the difference in pollination noted for these two forms.

The plants grow along the margins of lakes in shallow water where the depth may not exceed usually about one and a half or two feet. The leaves are strap-shaped and attain a length of approximately a foot or a little more. The American plant, on the contrary, appears to be much larger, with leaves up to a meter or more in length. The pistillate flower develops under water and is brought to the surface at the time of pollination by the elongated slender scape (Fig. 1d). The latter forms some surplus length which places the pistillate flower in a slanting position on the surface film of water. The floral parts of the flower are exposed on the surface and on account of the weight of these, the surface film forms a slight cup-like depression about each pistillate flower. At this time staminate flowers, floating on the surface, are moved along by currents or wind and may reach these depressions, when they tumble down and perforce strike against the stigmatic lobes of the pistillate flowers (fig. 1d). In this act a quantity of pollen is immediately shed on the stigmatic lobes, which upon examination show loose pollen grains, as large as 50  $\mu$ , sticking to their receptive surfaces. When, however, the water is disturbed, as frequently happens by the formation of strong waves, the pistillate flowers may suffer a temporary submergence, at which time the associated staminate flowers generally lose their contact with the stigmas and drift away. But, with the passing of the wave, the pistillate flowers are again exposed in the surface depressions. The transfer of pollen to the stigmatic lobes proceeds favorably during the short intervals when the surface of water is fairly quiet between successive waves. While many staminate flowers have merely a chance of "touch and go," the majority of them perhaps never reach the pistillate flowers but are washed ashore.

While the present observations are in general agreement with the details of pollination suggested by Wylie (1917) and strongly support the emphasis laid by him on the surface film in aiding pollination, the submergence of the pistillate flowers by the formation of waves does not appear to the writer to be a prime factor in the Indian form. In describing the events in pollination, Wylie suggests that submergence is undoubtedly beneficial to pollen transfer in the American form. However he notes elsewhere in the paper: "Attention should be directed to the fact that any degree of depression is helpful, and that complete submergence, although this probably occurs frequently, is not necessary to adequate pollination." The writer wishes to emphasize that pollination in the Indian form can go on uninterruptedly in the absence of submergence and in fact takes place largely during periods when the surface is not agitated by waves and strong ripples. It is, however, possible that submergence is indirectly helpful to some extent, in that it causes a dislodgement of old staminate flowers from the stigmatic lobes and thus offers chances for fresh staminate flowers to function in pollination.

The different degrees of importance attached to the submergence of the pistillate flowers in the American and the Indian forms may perhaps be properly ascribed to the relative size and structural differences in the flowers of these two forms. The divergent anthers appear to be perfectly suited to bring their pollen into immediate and direct contact with the stigmas in the surface depressions even

when the water is fairly still. Further, the pistillate flower is much smaller than in the American form, and it therefore presents a much smaller area at the surface of water for contact with the staminate flowers; furthermore, during submergence it is not capable of retaining the staminate flowers in such large numbers or as generally as in the American form, which has a much larger area of depression and the stigmas are sharply coiled.

The earlier work of Kerner (1891) appears to be, as already suggested by Wylie (1917), "highly generalized, and perhaps intended to convey only a general account of the pollination in this plant." Kerner

has ignored the special agency of the surface film in the process of pollination and figures a level water surface with the pistillate flower held high straight above water as if by a stalk. The cup-like depression, which is so essential in capturing and retaining temporarily the staminate flowers, was entirely overlooked by him. His account of pollination appears to be based on an unsound principle, for the surface depression is a natural phenomenon formed on account of the purely physical property that the surface film of water has in relation with any floating object that is not wetted by water. Further, the arrangement of the flowers themselves on a level water surface, as depicted by him, does not seem to be conducive to adequate pollination.

INFLUENCES OF POLLINATION ON THE BEHAVIOR OF THE PISTILLATE FLOWERS.—Turning now to the second aspect of this paper-namely, the behavior of the pistillate flowers, prior to and after pollination—the following is a description of some features noticed by the writer. The pistillate flower develops under water, and at the stage when its ovules are in the megaspore mother cell condition, it is a little over 2 mm. long, with a very short stalk measuring about a millimeter (fig. 8a). The stalk gradually increases in length until it brings the pistillate flower to the surface of the water. The increase in length is largely due to an elongation of the individual cells of the scape; in a number of instances it was found by measurements that the cells had increased by about 40 to 50 times their original length (fig. 8c, 9). It may be noted here that the pistillate flower of Elodea Wylie (1904) also reaches the surface of the water by cell elongation, at the time of pollination, of that part of the flower above the ovary.

When the pistillate flower has just reached the surface of the water, it is nearly vertical but later gradually assumes a more or less horizontal position by the further increase in the length of the scape. The stigmatic lobes spread out in about two to four hours, and pollination is effected in favorable circumstances in about four to six hours. After pollination the scape of the pistillate flower undergoes a spiral torsion, which is first evident at the base of the ovary. This is followed by the formation of a number of coils in the scape. These coils then draw closer and tighten, and the pistillate flower retreats under water, where the fruit is developed. Müller (1878) pointed out that the anatomical structure of the scape includes two vascular strands, of which one is smaller than the other; if the growth of these two strands, as suggested by Svedelius (1904), is different, the result would be a coiling of the scape. In a quiet aquarium where the plants were kept for observation, it was found that subsequent to pollination the pistillate flower had retreated under the surface of water by a centimeter in about three hours, and in the course of another three hours it was 7 cm. below. This rate of retreat of the pistillate flower need not, however, hold good in natural surroundings.

A change in the depth of water, as, for example, when the plants are transferred from their natural surroundings to aquaria, brings about a corresponding change in the length attained by the scapes of the developing pistillate flowers. In the case of a plant which had a number of pistillate flowers some of which had already developed into fruits in the natural surroundings, with the scapes attaining their normal length of about 46 cm., one developing young flower was marked for observations. The plant was then transferred to the aquarium where the depth of water was 16 cm.; when the marked pistillate flower finally came to the surface of the water in the aquarium, it had developed a scape only 18 cm. long. Chances for pollination were immediately offered by introducing a number of staminate flowers on the surface of the water after the stigmas had completely opened; in about three hours, during which time pollination occurred, the flower commenced to retreat under water.

If, on the other hand, pollination is prevented, as was done in other similarly marked pistillate flowers, they remain on the surface of the water for a prolonged period after which they begin to retreat, rather slowly, by the formation of only a few loose coils in the scape. Sometimes, however, the length of the scape may continue to increase afresh even after the pistillate flower is completely exposed on the surface of the water and has been lying thus for some time; in one instance it was found to have developed a scape fully 40 cm? long while the water in the aquarium was only 16 cm. deep. When chances for pollination were provided, even at this late stage, the pistillate flower behaved normally and promptly developed into a fruit. In the complete absence of pollination the flowers sank only a little under water, and the formation of the fruit was altogether suppressed. Wylie (1917) states that "the scapes will coil somewhat without pollination, so the retreat of the seed-bearing flower is the final step in pollination if the pollen-bearing flowers are present." Under normal conditions following pollination the pistillate flower sooner or later retreats under water and forms the fruit.

Discussion.—In considering the importance of the surface film in pollination in Vallisneria it is desirable to point out the few other recorded instances of a similar nature. Cowles (1911) mentions the film pockets formed on the surface of the water but does not enter into a further discussion. Wylie (1904), in discussing the phenomenon of pollination in Elodea canadensis, has fully described the surface depression of the water about each flower into which slide the floating pollen grains. The case of Elodea is somewhat different from that of Vallisneria, for in the latter it is the free floating staminate flowers themselves and not pollen grains scattered loose on the surface of the water which are gathered in the surface depressions. The process of pollination, however, is essentially similar in both in that the surface depressions play an important rôle. Svedelius (1904), on the other hand, does not make

any reference to the possible part played by the surface film in the pollination of Enalus acoroides, in which he states that the cross folds of the long and delicate petals of the pistillate flowers serve to capture and retain the staminate flowers as they arrive floating on the surface of the water. But Enalus presents a modified case in that the plants live in the open sea where the currents are very strong and may often reach a speed of 5 to 6 knots in an hour (Svedelius, 1904), so that a very effective device for retaining the staminate flowers for pollination would be of advantage. The most complete and also the latest treatment of the subject of surface pollination is by Wylie (1917), who has emphasized the importance of the surface film in the pollination of Vallisneria. Kerner (1891), as was pointed out by Wylie (1917), failed to note any surface film relations in the pollination of this plant.

The present account of pollination in Vallisneria. the Indian form of which differs very considerably in several essential features from the American form, is in general corroborative of the observations of Wylie (1917). It differs only in one respect which appears to the writer to be of sufficient importance to be stressed—namely, in the influence of submergence of the pistillate flowers in aiding pollination. As already noted, it seems to be the size and the structural differences in the flowers in the Indian form that are responsible for this difference. A reinvestigation of the form studied by Kerner will doubtless show it behaved very much like the Indian form, for our species seems to agree more closely with the Vallisneria of Europe in the plan of the staminate flowers which have the widely divergent stamens figured by Kerner and noted by Svedelius (1932). The pistillate flowers are also more like the European type and are much smaller than in the American form. The differences between the various forms are so marked as to point out the desirability of a taxonomic review of the genus. This, however, does not fall within the scope of the present study.

In concluding the present study of pollination in *Vallisneria spiralis*, the remarks of Wylie (1917) in the introduction to his paper on this interesting

phase in the life history of the plant may be restated: "Living vegetatively as a submersed aquatic, its dioecious flowers are brought together at the surface of the water in most ingenious fashion. These highly specialized flowers present the strongest contrasts, not only in size and structure, but in behavior as well, and give this plant its rank as one of the climax types with respect to floral differentiation. Specializations of such evident advantage for crosspollination in a form so admirably situated for vegetative propagation seem to emphasize the importance of sexuality, or at least of seed production, in the higher plants."

#### SUMMARY

The account of pollination in Vallisneria spiralis presented here differs slightly from that given by Wylie (1917). While submergence of the pistillate flowers may further pollination in the American form, it is not of such significance in the smaller Indian form but may be indirectly helpful in bringing fresh staminate flowers into the depressions about the pistillate flowers. The present account, otherwise, supports the observations of Wylie with regard to the part played by the surface film forming the depressions to capture the staminate flowers. Since the Indian form is more like the European, the present findings indicate that the account of pollination by Kerner (1891) may be regarded as somewhat generalized. The differences in flower structure between the various forms from different regions call for a taxonomic review of the genus.

The second part of the paper concerns the influences of pollination on the behavior of the pistillate flowers. The period ordinarily open to pollination is several hours, and the subsequent rate of retreat of the pistillate flower under water is very slow at first, less than a centimeter per hour. Pistillate flowers in the lake had scapes 46 cm. long; when the plants were transplanted to an aquarium with water 16 cm. in depth, the scapes attained a length of only 18 cm.

# RELATION OF LATITUDE TO CERTAIN PHASES OF THE GROWTH OF TIMOTHY $^{\rm 1}$

## Morgan W. Evans

AN EXPERIMENT was conducted for the purpose of determining the relation of latitude to certain phases of the growth of early, medium, and late timothy (Phleum pratense L.) and to the progress from one latitude to another of their seasons for heading, blooming, and maturing (Evans, Allard, and McConkey, 1935). This experiment was conducted at ten stations at different latitudes, as shown in table 1. In addition to the recorded variations in latitude, data are presented in regard to the longitude, altitude, mean annual temperature, and the length of the longest day at each station; no information was obtained in regard to variations in soil type, rainfall, humidity, or other factors than those mentioned which may have affected the results. In this report the results of a second, related experiment are also presented, which show the effects of latitude upon the yields of hay produced by early, medium, and late strains of timothy.

Because of the nature of this investigation, the results presented in this report have been made possible only through the cooperation of a number of widely separated collaborators. Data were obtained by Professor George E. Ritchey, associate agronomist, Division of Forage Crops and Diseases, Bureau of Plant Industry, United States Department of Agriculture, Gainesville, Florida; Mr. R. E. Stitt, assistant agronomist, Division of Forage Crops and Diseases, Bureau of Plant Industry, United States Department of Agriculture, Statesville, North Caro-

CONDITIONS DEPENDENT UPON LATITUDE WHICH AFFECT THE GROWING HABITS OF TIMOTHY.—According to the older biological writings, temperature is the most important factor in determining the distribution of plants and animals (Shelford, 1932,

b Approximate.

p. 147). According to Kendeigh (1932), Reaumur (1735) calculated the season for the appearance of plants and animals by summing the accumulated degrees of temperature above freezing. Later Merriam (1894, 1899) mapped life zones in North America. In determining the boundaries of these zones, Merriam used as effective degrees of temperature only those above 43 degrees F. (6 degrees C.), which DeCondolle in 1835 had shown to be the threshold temperature at which wheat will germinate (Kendeigh, 1932). In Hopkins' Bioclimatic Law (Hopkins, 1918), as in earlier theories, a predominating influence was assigned to temperature. According to this law, if other conditions, such as altitude, topography, etc., are uniform, the time of blooming of any species of plant should progress from south to north, along the same degree of longitude, at the uniform rate of one-fourth of a degree of latitude each day.

Failure of the older theories to predict accurately the progress of the season.—Shelford (1932) and Kendeigh (1932) have shown that the life zones described by Merriam do not coincide with the plantanimal communities recognized in modern ecology.

Table 2 contains records for 1928 (Evans, 1931) of the dates upon which florets began to bloom on plants of an early selection of timothy at six stations from Savannah, Georgia, to Fairbanks, Alaska. The table also shows the predicted dates when the plants at the stations north of Savannah should have begun to bloom, according to Hopkins' Bioclimatic Law. In general, the farther north the plants were grown, the greater numbers of days did they bloom before the predicted dates. These results indicate that some factor other than temperature, and not recognized in the Bioclimatic Law, had an important influence upon the time of blooming.

Relation of temperature to the time of blooming.—The effects of seasonal variations in temperature upon the time of blooming of ordinary American timothy is shown in data obtained at the Timothy Breeding Station<sup>2</sup> at North Ridgeville, Ohio,

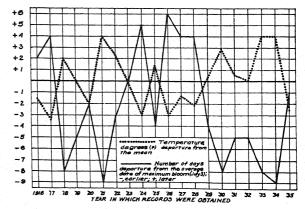

Fig. 1. Relation of the mean temperature during April, May, and June to the date the maximum percentage of plants were in full bloom. The records were obtained from 1916 to 1935.

in each year from 1916 to 1935, excepting 1919. Figure 1 shows the average number of degrees F. daily departure from the mean temperature during April, May, and June;<sup>3</sup> it also shows the number of

<sup>&</sup>lt;sup>a</sup> Hopkins states: "Other things being equal, the variation in the time of occurrence of a given periodical event in life activity in temperate North America is at the general average rate of four days to each 1 degree of latitude, 5 degrees of longitude, and 400 feet of altitude, later northward, eastward, and upward in the spring and early summer, and the reverse in late summer and autumn" (Hopkins, p. 7, 1918).

<sup>b</sup> Approximate.

days earlier (-) or later (+) than July 3—the average date of maximum bloom during these 19 years—when the date of maximum bloom occurred in each season.

In each year excepting 1920 and 1935 when the average temperatures during April, May, and June were above the mean, the date when the maximum number of plants were in full bloom occurred earlier than the median date; when the daily temperatures were below the mean, the date when the maximum number of plants were in full bloom was later than the median. For each degree of average daily temperature above the mean, the average date of full bloom was advanced two days earlier than the median, and for each degree below the mean the date when the maximum number of plants were in full bloom was delayed two days.

Rôle of length of day in relation to the growth of timothy.-Garner and Allard (1920) showed that in many species of plants development is profoundly affected by differences in the periods of daily illumination. In timothy (Evans and Allard, 1934) late plants require longer days for the development of culms and inflorescences than early ones. Roberts and Struckmeyer (1937, p. 647) have found that timothy, like many other kinds of plants, gives different photoperiodic responses at different temperatures.

In an experiment conducted at Washington, D. C. (Evans and Allard, 1934), early timothy plants produced normal culms and inflorescences with from 12 to 12.5 hours' illumination, while very late plants required 15 hours or more for these processes. Under natural lengths of day, the first florets bloomed on plants of 19456, the earliest selection, on June 3; on plants of 6127, a selection blooming about the same time as ordinary timothy, on June 19; on 19460, the next to the latest selection, on July 22. With the daily illumination increased to 18 hours, on the plant of 6127 the first florets bloomed on June 3, and on 19460, on June 4. When grown under a sufficiently long day, therefore, the medium and the late selections bloomed as early, or very nearly as early as the selection (19456) which, when grown under natural conditions, was the earliest in the

The more rapid development of many kinds of plants at northern latitudes than at places relatively far south (Albright, 1933) is due largely to this acceleration which occurs when they are grown under the very long days of spring and summer in the far North.

PROCEDURE.—Nine F. C. selections of timothy were used, ranging with fairly uniform gradations from very early to very late. With the exception of the three latest strains, which were of Danish and Russian origin, these selections were derived from ordinary American timothy. Number 6743 heads.

\* The F. C. selections have been assigned accession numbers by the Division of Forage Crops and Diseases, Bureau of Plant Industry of the United States Department of Agriculture.

blooms, and matures at approximately the same time as ordinary timothy; numbers 19456, 19458, and 11902 are earlier, and numbers 12421, 19416. 19459, 19460, and 28023 are all later than ordinary American timothy.

The plants were sent from the Timothy Breeding Station in 1934, then located at North Ridgeville, Ohio, to the nine other stations, extending over more than 28 degrees of latitude. Since the plants had been propagated vegetatively from the original plant of each selection, variations, which would have occurred if the plants had been grown from seed, were eliminated.

The characteristics observed include: the habits of growth of the stems, whether upright, decumbent or procumbent; the lengths of the stems; the extent of development of inflorescences; and the dates when the first florets bloomed. The relative times of heading, blooming, and maturing of different selections were not greatly different (Evans, 1922). Records obtained in 1936 and 1937 do not differ greatly from those in 1935, which are presented in this

In the experiment conducted at Lexington, Kentucky, and at North Ridgeville, Ohio, the data in regard to the yields of hay were obtained at each

station from replicated broadcast plots.

HABITS OF GROWTH OF EARLY, MEDIUM, AND LATE PLANTS AT DIFFERENT LATITUDES .- The plants of any selection of timothy, especially late ones, may assume different forms at different latitudes.

At Statesville, North Carolina, at latitude 35.8 degrees, several of the early selections produced upright culms; the plant of 11902, which is a few days earlier than ordinary timothy (fig. 2A) had essentially the same appearance as plants of the same selection grown at stations farther north. On the other hand, at Statesville, plants of very late selections, as 19460 (fig. 2B), produced only short decumbent culms. This same very late selection, grown as far north as Beaverlodge, Alberta, Canada, at 55.2 degrees, produced upright culms, and the form of the plant was like that shown in figure 2C.

Early selections were found to have upright habits of growth, both in the North and in the South. Late selections had decumbent culms in the South -being increasingly decumbent as the selections were increasingly later. At the stations farthest north, on the other hand, even the latest selections had upright culms. At mid-latitudes, the plants of the very late selections had intermediate habits of growth.

Lengths of the stems.—The length to which the longest stem of each plant grew is recorded in table 3.

At the southern stations, the lengths of the culms were gradually shorter as the time of heading, blooming, and maturing of the plants became later. At mid-stations plants which bloomed and matured at approximately a medium date in general produced longer culms than either the early or the late selections. At the two most northern stations from

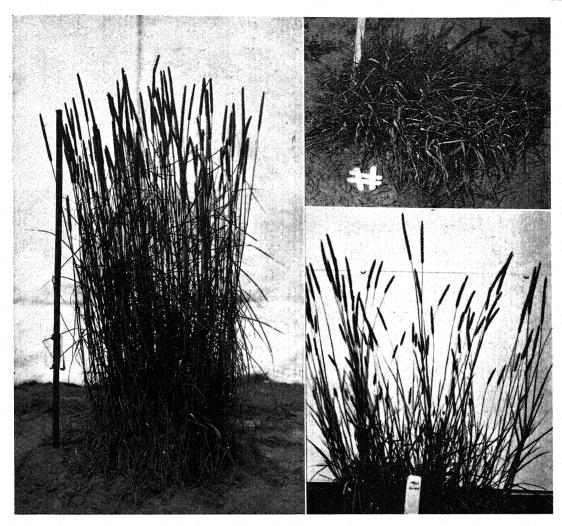

Fig. 2.—A (left). Timothy number 11902, somewhat earlier than ordinary timothy, grown at Statesville, North Carolina, at latitude 35.8.—B (upper right) and C (lower right). F. C. 19460, a very late selection of timothy.—B. Grown at Statesville, North Carolina; the plant had short, decumbent stems and no inflorescences.—C. Grown at Beaverlodge, Alberta, Canada, 55.2 north latitude; the plant produced upright culms and inflorescences.

which records for all selections were obtained, the lengths of the longest culms of the two latest were only five to six inches shorter than those maturing at a medium time.

Differences in the lengths of the stems at a southern and at a northern station are illustrated in figure 3.

Development of the inflorescences.—At Gainesville, Florida, only the earliest selection, 19456, produced inflorescences; the later ones produced only short, more or less decumbent, barren shoots. At Belle Glade, Florida, also, 3 degrees farther south than Gainesville, where all these selections were planted, number 19456 was the only one which produced culms with inflorescences. At Statesville, North Carolina, all excepting the two latest selections produced inflorescences. At Washington, D. C., at latitude 38.9 degrees and at North Ridgeville, Ohio, at 41.4 degrees, although all selections pro-

duced inflorescences, yet on the three latest ones a large proportion of the culms were barren. Farther north, as at Beaverlodge, Alberta, where the culms of all selections were upright, even the latest plants produced large numbers of inflorescences.

Time of blooming.—Table 4 shows a greater spread in the time of blooming at the southern than at the northern stations.

The season of blooming for the earlier selections progressed from south to north. On the other hand, each of the four latest selections began to bloom at some station north of the most southern one, and from there the season for blooming progressed both toward the north and also toward the south.

The data presented in the preceding paragraphs are from a series of stations extending in a general direction from southeast to northwest. Similar results were obtained in 1933 at La Jolla, California, and at North Ridgeville, Ohio, 8.6 degrees far-

ther north and 35.25 degrees farther east; numbers 19456, 19458, and 11902, all early selections, began to bloom at La Jolla on May 6, June 10, and July 9, and at North Ridgeville on June 5, June 8, and June 10, respectively. The season for blooming of selections 19458 and 11902 progressed from the northern station toward the southern one; the season progressed from the south to the north only for the earliest selection.

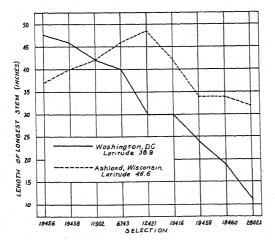

Fig. 3. Lengths of longest stems of early, medium, and late timothy plants at two latitudes. The selections are arranged in order of time of blooming, from the earliest at the left to the latest at the right.

YIELDS OF HAY AT DIFFERENT LATITUDES.—In an experiment conducted in 1933, 1934, and 1935, at Lexington, Kentucky—near the latitude of Washington—records were obtained of the yields of hay produced by two F. C. selections of timothy which, at North Ridgeville, Ohio, were about four and five days earlier, respectively, than ordinary timothy—i.e., numbers 11901 and 12468—and by two late

selections, numbers 3937 and 12368, which at North Ridgeville are about six and seven days later, respectively, than ordinary timothy.

The average yields of hay per acre at Lexington, Kentucky, are presented in table 5. The yields of both early selections were greater and of both late selections were less than the yields of ordinary timethy.

The same strains of timothy were grown at North Ridgeville in 1931, 1932, and 1933. In the latter year, ordinary timothy at North Ridgeville produced 2908 pounds per acre, compared with a yield of 1660 pounds at Lexington. The larger yield at North Ridgeville than at Lexington is apparently correlated with the tendency of the stems to grow to greater lengths, and for a larger proportion of them to produce inflorescences at northern than at southern latitudes.

If the yields of ordinary timothy are assumed to be 100, then at the northern station, the average yields of the early and of the late strains were 104 and 108, respectively; at the southern station, 138 and 76, respectively.

DISCUSSION OF THE EXPERIMENTAL RESULTS.—In order that the plants of any strain of timothy may produce culms and inflorescences, both the daily temperatures and the lengths of day must equal or exceed the minimum requirements for that strain. As long as either condition fails to meet the required minimum, the plants remain in a vegetative state. In the South, temperatures are suitable for reproductive development in early spring, but the days are too short. In the North, days become of suitable length earlier than in the South, but temperatures are too low for growth and development.

Progress of the season from one latitude to another.—The progress of the season for blooming is shown in table 4 and figure 4.

For the earliest strains of timothy, at the southern border of the timothy growing area in the north-

ern hemisphere, the days are of sufficient length for the development of culms and inflorescences when or soon after the weather has become warm enough for spring growth. For these early strains, the season for heading, blooming, and maturing progresses northward at a gradually accelerated rate as the season advances.

	Average	•	1287

<sup>\*</sup> Records obtained by Professor E. N. Fergus of the Kentucky Agricultural Experiment Station.

For a medium maturing strain, as 6743, the season for heading, blooming, and maturing, is at first delayed, after temperatures are suitable, until the days become of sufficient length, but eventually begins at the southern border of the timothy area, progressing northward, at first slowly then at a constantly accelerated rate.

For the latest strains of timothy, the time for heading, blooming, and maturing is delayed for an even longer time. The plants begin to bloom, not at the southern border of the timothy growing area, but at a latitude where suitable temperatures, and suitable lengths of day first occur. At or near the place where the minimum requirements of both conditions are first fulfilled, the plants of any very late strain of timothy begin to bloom, and the season for blooming then progresses in both directions—toward the north as the temperatures become higher, toward the south as the required lengths of day occur.

Under natural conditions, where timothy is adapted, possibly the season for blooming may nowhere progress from north to south, as in this experiment. In the southern part of the timothy area

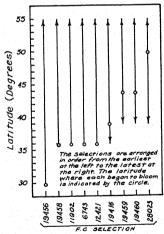

Fig. 4. Progress of the season in 1935 for blooming of different selections of timothy.

the very late strains do not reproduce themselves through seeds. Even for some distance north of the southern limits where they produce culms with inflorescences, the florets bloom late, and little or no seed matures. Consequently, if introduced there,

<sup>(</sup>c) No plant of this number was grown.

they would gradually be replaced by biotypes better adapted to such conditions.

Adaptation of early, medium, and late varieties at different latitudes.—The degree of adaptation of any variety of timothy at any latitude depends very largely upon how well the characteristics of the plants, especially their adaptations to days of different lengths, are suited to the conditions.

In the North, either early or late varieties of timothy may be grown, since the days are of sufficient length for the development of plants of either type. The choice of a variety would depend largely upon farm management practices.

In the South, because of the short days of early spring, the time when late varieties begin to produce culms and inflorescences is delayed until so late in the season that the culms do not attain full length, and the yields of hay are small. The choice of varieties for the southern part of the timothy growing area, consequently, is necessarily restricted to those which are early.

#### SUMMARY

For the purpose of obtaining information in regard to certain phases of the growing habits of timothy as affected by latitude, plants of nine selections, ranging by fairly uniform gradations from very early to very late, were grown at each one of ten stations located at intervals extending from Gainesville, Florida, to Fort Vermilion, Alberta, Canada.

In the South, selections which are progressively later had progressively shorter stems; the stems of the latest selections are more or less procumbent there. In the North, the stems of the later selections grew to as great, or even greater lengths than those of the early selections.

The time of heading, blooming, and maturing is determined largely by the temperatures and by the lengths of day. Late selections require longer days than early ones for the production of culms and inflorescences.

For the earliest selections, the season for blooming progressed from south to north. For the latest selections, blooming occurred first at some mid-latitude; from this latitude, the season for blooming progressed both toward the North as the temperatures became suitable for growth and toward the South as the number of hours of daily illumination gradually increased.

At a northern station, both early and late selections produced relatively large yields. At a southern station, late selections produced smaller yields of hay than early selections, which are better adapted to the relatively short days occurring there.

## RELATIONS BETWEEN TISSUE ORGANIZATION AND VEIN DISTRIBUTION IN DICOTYLEDON LEAVES <sup>1</sup>

Robert B. Wylie

This paper deals with certain relations between leaf structure and the distribution of minor veins in the blade. In connection with work on the wound responses of foliage leaves the writer built up several series of slides which were equally favorable for the study of normal leaf tissues. It seemed from reviewing these preparations that vein spacing was often related to mesophyll organization. A careful analysis of leaves of three series of plants seemed to confirm this generalization and revealed a fairly close correlation between the photosynthetic and conductive tissue of the blade in these species.

Several investigations have dealt quantitatively with the development of the minor venation in the leaf blade. Zalenski (1902), using leaves cleared in chloral hydrate and mounted in glycerin, called attention to variations in total length of vein per unit area in plants of given species even in similar habitats. This led to his later paper (1904), which is discussed at length by Maximov. He demonstrated a wide range in the structure of leaves distributed vertically along a single stem. On shrubby or herbaceous plants of moderate size he found leaves of higher insertion successively more xeromorphic with progressively greater vein length per unit area than those lower on the same stem. While this feature was associated with several other structural differences in the leaves investigated, he considered these vein specializations as most closely correlated with cell size in the different leaves.

Schuster (1908) surveyed a considerable number of plants, giving attention to differences between sun and shade leaves. With few exceptions, shade leaves were larger than sun leaves of the same species, but the shaded leaves had reduced venation, in terms of total vein length per unit area of blade, compared with those in the sun.

Benedict (1915) made an intensive vein study of a few plants but concerned himself particularly with Vitis vulpina. He held that vein spacing (which he termed the vein-islet) for leaves of this species was correlated closely with the plant's age, diminishing regularly through successive years after the launching of a new plant from an embryo started by fertilization. His records were made photographically by transmitted light, using untreated living leaves, which method probably failed to record some of the lesser veinlets. While he noted the earlier work of Zalenski (1902), he does not include the very important paper by that writer published in 1904.

Strain (1933) recently made a study of the types of vascular elements in the vein endings of a large number of species, by clearing whole leaves, cotyledons, and petals. He finds type patterns of tracheal organization rather than variations due to environ-

<sup>1</sup> Received for publication January 16, 1939.

ment. Vein endings of sun leaves and shade leaves did not differ within the species, either in arrangement or shape.

MATERIAL AND METHODS.—The leaves, cut into small rectangles, were mostly killed and preserved in 3 per cent formalin, imbedded in paraffin, and sectioned (12 µ thick) in both transverse and paradermal planes. Leaves from trees, shrubs, and herbaceous plants were included in collections from a number of widely separated regions. In this paper dicotyledon leaves of three series are discussed: (1) Iowa woody plants (table 1), (2) Iowa herbaceous plants (table 1), and (3) a group of broad-leaved woody plants, mostly evergreens, from the Pacific coast regions, including plants from western Washington, Oregon, and southern California (table 2). Sufficient numbers of species were included to constitute a representative sampling for each of the three groups surveyed.

In all instances sun leaves were selected, or in the case of shade plants, those with average illumination. While both trees and shrubs are included in the woody series, all collections were uniformly taken at such height as to be within reach from the ground. While leaves of this level may differ from those higher on the same plants, comparisons between taller plants would be fairer if leaves of like exposure and of corresponding height of insertion were used. While this survey includes several plants not native to Iowa, only such were taken as have long and regularly grown in this state. The Pacific coast species are all native and nearly all of them evergreen.

In this study the tissues of the blade, between veins, have been resolved, as accurately as possible, into vertical and horizontal elements. The epidermal covering involves the only continuous cell layers of the blade. While protective in some degree, due primarily to the cuticle, these layers sustain a basic relation to the other tissues through their mechanical and conductive functions. The upper and lower epidermal layers together constitute about one-fifth of the leaf's volume in each of the three groups. This ratio would be considerably increased in leaves having multiple epidermis, but these are not included in this study excepting only Berberis nervosa, which has a subdermal mechanical layer of cells 15  $\mu$  thick.

The spongy mesophyll, like the epidermis, is primarily a zone of horizontal integrity and is generally an intermediary tissue between the more specialized photosynthetic cells and adjacent minor veins. This tissue can be correctly interpreted only from sections parallel with the epidermis, as evidenced by its inchoate appearance in transverse sections of the leaf. It carries some of the chlorophyll and usually has outstretched arms from each cell

which unite with similar extensions from adjacent cells, leaving large intercellular spaces (fig. 2, 4, 6). Its porosity (in the dorsiventral blade) permits ready diffusion of gases to and from the palisade. A high proportion of spongy mesophyll because of its lateral connections between cells simplifies conduction between veins.

The palisade parenchyma offers sharp contrast to the epidermis and sponge (fig. 1, 3, 5). Its cylindric or prismatic cells, elongated at right angles to the leaf surface, have limited lateral contacts and thus present a much greater surface against intercellular space involving at times a high transpiration rate (Turrell, 1936). The palisade type of mesophyll complicates conduction problems and involves both increased amounts and indirect routes of transfer between major photosynthetic cells and conductive tissues and thus becomes a factor in vein distribution.

Various measurements of the leaves surveyed are summarized in tables 1 and 2. While several of the columns need no explanation, it should be recalled that the distance between veins or the intervascular interval (Int. vas.) is based upon measurements from xylem to xylem. The width of the border parenchyma (Bor. par.), which shares in some degree in the conductive work, is also given in all cases. Column SEE is the total thickness of the epidermal layers together with that of the spongy mesophyll, if present. The thickness of blade (Total thick.) was measured between veins. It should be noted that each number in the tables represents an average value based upon ten to twenty or more measurements of the item in question. The final columns at the right show the percentile distribution of blade thickness between the cell layers of greater horizontal integrity, the sponge and epidermis (SEE), and that given over to palisade (Pal.) with its vertically elongated cells. Since the different tissues were measured independently, the sum of the numbers approximates 100 per cent but may vary slightly from unity. In these tables the species are arranged with respect to their intervascular intervals, the one with widest spacing between veins is placed first and others in order, the last having least distance between vascular strands. Thickness of cuticle is included in epidermal measurements and in total thickness of blade.

Discussion.—Due to lack of uniformity of vein size and pattern in different leaves, the term intervascular-interval has been used to denote the mean maximum distance between veins (xylem to xylem) as seen and measured, using paradermal sections. It should be noted that the minor venation is closely integrated, whatever the pattern, and constitutes a plexus of channels that extends far and wide in the

<sup>\*</sup> SEE is the combined thickness of spongy mesophyll and epidermal layers.

blade except as interrupted by larger veins. Some leaves have definite polygonal islets (fig. 7), but in the majority of species the intrusion of vascular branches, which are often repeatedly divided, results in a vein system which has little resemblance to the net-like type (fig. 8–10). An average of the measurements across carefully selected major intervals gives a fairly accurate interpretation of the vascular distribution of a given leaf.

The border parenchyma as a sheath about minor veins shares in the transfer of materials and is intermediary between mesophyll and vein. Dorsiventral extensions of this bundle investment increase the number of cell contacts and may even reach one or both of the epidermal layers. The importance of the border parenchyma has not been adequately stressed by botanists. However, owing to its relative uniformity, it is not given special consideration in this paper, and its radial thickness is included in the intervascular-interval.

By way of factual summary it may be stated that this survey includes leaves from plants of wide geographic and taxonomic distribution, ranging from soft, mesophytic, shade plants to sclerophylls of desert areas in California. Among them are herbs, shrubs, and trees of great diversity having leaves of wide range in size, form, thickness, texture, and longevity. While the epidermal layers vary less, the mesophyll organization ranges from predominant sponge to pure palisade. The venation of these three

groups of dicotyledons offers similar diversity of pattern and distribution with no type peculiarly distinctive of any habit or habitat. The arrangement in any of the groups may be that of the simple islettype or may involve modified patterns having elaborately branched minor veins. In spite of the wide fluctuations in all parts and tissues among the leaves of the 66 species covered in this survey, an attempt has been made to correlate blade structure and vein distribution. While other factors obviously are involved, measurements reveal for each of the groups a significant relation between the relative amounts of vertical and horizontal tissues in the blade when compared with the intervals between veins of the same leaves. Variations in the orientation of the mesophyll cells are likely to be associated with readjustments of the intervascular-interval. Increasing proportions of palisade tend, other things being equal, to force veins nearer together, while greater relative amounts of spongy mesophyll permit wider separation of vascular channels.

The broad leaved dicotyledons of the Pacific regions for the 20 species surveyed had nearly equal amounts of paradermal tissues and palisade mesophyll, with a mean intervascular interval of  $140.2~\mu$  (table 2). For this group the coefficient of correlation between blade organization and vein distribution was .684 with a probable error of  $\pm 0.0804$ . The Iowa herbaceous plants, represented by 24 species, had relatively more paradermal tissues in the

<sup>&</sup>lt;sup>a</sup> SEE is the combined thickness of spongy mesophyll and epidermal layers.

blade (61 per cent) and had a much wider vein separation with a mean intervascular interval of 136.0 µ (table 1). For these the coefficient of correlation was .648 and the probable error  $\pm 0.0803$ . The Iowa woody plants, 22 species, constitute a somewhat intermediate group, with approximately 55 per cent of the blade tissues horizontally integrated, and had a mean intervascular interval of 112.1  $\mu$  (table 1). For this group the coefficient of correlation between tissue arrangement and vein separation was .735, with a probable error of  $\pm 0.0597$ . Smaller groups of species from other areas, similarly surveyed, gave relatively higher correlations between blade structure and vein separation, but the results were not included in this paper because of limited samplings. It seems, however, that conclusions based upon 66 species, representing three groups of such diverse habit and habitat might be considered significant.

That other and important factors enter into the problem of minor vein distribution is obvious. Total leaf thickness, cell size, compactness of tissues, relative epidermal thickness, and possibly the nature of the border parenchyma should influence internal tissue relations. Most of these, however, would operate through their effects upon conduction to and from veins. For example, many leaves with large amount of palisade have increased lateral contacts between these cells, thus simplifying paradermal conduction. An analysis, to be complete, should measure the degree or amount of lateral integration between cells of all blade tissues and should evaluate the effects of added cell layers as found in thicker leaves. The well known differences between different parts of

the same blade should govern the selection of material. The thickness of the cuticle, which is considerable in broad leaved evergreens, has in this study been included in epidermal thickness though it is obviously not helpful in lateral conduction. Any considerable differences between the paradermal and vertical dimensions of the border parenchyma likewise should be taken into account. Obviously, cell size has an important bearing on conduction problems, as noted by Zalenski (1904), and illustrated by Tellefsen (1922).

It seems probable that the vascular system of a leaf develops conservatively, to be extended within limits in relation to conduction demands foreshadowed by conditions during later leaf development. The differences between the mesophyll of sun and shade leaves on the same plant are well known, but it is not so generally recognized that the venation is correspondingly modified, as has been shown by Schuster (1908) and others. This suggests that during the development of a leaf its tissues follow a more or less specific pattern but are modified in some degree by local conditions during ontogeny. The deepening shade in the developing crown of a tree introduces gradual differences in the amount of light reaching interior leaves. The cells primarily concerned with the development of the minor veins retain longest a capacity for normal cell division. Mounts (1932) has shown for Vitis vulpina that the cell layers giving rise to the minor veins are the last to mature. This prolonged capacity for cell division in this zone aids the leaf in modifying its vein pattern to the type of mesophyll being developed in that particular leaf. The dominant hereditary pattern and the probability that differences may be impressed upon leaf rudiments through bud position and exposure during early stages need not hinder subsequent adjustments of veins and tissues during later development under somewhat different situation.

The relatively long time required for growth of a leaf favors some adjustment of the given organ in relation to its particular location. If the period of development were too brief, days rather than weeks, a number of successive cloudy days at a critical period might give the leaf a pattern less suited to its average adult exposure. A longer period of plasticity permits closer approach to the type fitted to the leaf's immediate environment. It may be unfortunate for some deciduous trees of the upper Mississippi valley that their leaf pattern is worked out so early in the season, at a time of cooler weather and more frequent rains and before the increased and prolonged transpiration demands of the summer have developed.

The palisade, whatever its advantages, involves problems relating to material transfer. As the center of the leaf's activity, its extensive surface promotes transpiration which forces water transport, and the photosynthate must also be carried out. While the elongation of its cells favors vertical (lengthwise) movement of materials within these cells, their limited lateral contacts force endwise entrance and exit through terminal walls that are restricted in area compared with the volume of these long cells. This not only lengthens the total distance for the transfer of increased loads but forces a right angle route, first downward to the spongy mesophyll, or the plane of the minor veins, then laterally to the border parenchyma.

The upper epidermis may help with conduction to or from the adjacent palisade. This covering layer has closely integrated cells with lateral walls usually pitted, thus favoring movement of materials in the horizontal plane. Its vascular connections are aided by dorsal ribs from some of the lesser veins. But the spongy mesophyll, when present, is the chief intermediary between palisade and vein. The junction plane shows the lower ends of the palisade cells closely grouped and connected with the sponge. The lateral unity of the spongy mesophyll and the fact that with rare exceptions the minor veins lie in this zone favors lateral movement to or from vascular strands. Even in the leaves which seem to be all palisade, paradermal sections often reveal a thin layer of closely connected cells in the plane of the veins (fig. 4). It seems fairly clear that the palisade/ sponge ratio is related through conduction problems to the distribution of veins in the blade.

The intervascular-interval, carefully measured from paradermal sections, seems a useful criterion in the interpretation of leaf organization. While there may be a considerable personal element in the evaluation of the more complex vein patterns, it stresses vein-spacing or, more accurately, the width

of tissue associated with conductive channels, rather than total length of veins (of all categories) per sample area. Since veins are seldom in the form of simple meshes, the term "vein-islet" is difficult in general application. Through a study of the intervascular-interval the blade, regardless of vein pattern, is resolved into narrow bands of chlorenchyma about the minor veins.

The proximity of veins reveals the limited distance through which conduction may take place from cell to cell in sufficient amount for the needs of an active leaf. The average distance between the minor veins for the 66 species included in this survey is about 130  $\mu$ . Since this is twice the maximum conduction distance, measured in the paradermal plane, the average width of tissue bordering the veins is but 65 μ. This distance is increased of course for cells that lie above or below the plane of the minor veins which are usually embedded in the spongy mesophyll. The functional unit of the foliage leaf is a limited width of tissue, mainly chlorophyll bearing, associated with each minor vein, and there exists in general a close relation between mesophyll organization and vein distribution.

#### SUMMARY

An analysis of leaf structure for three groups of dicotyledons, including 22 Iowa herbaceous plants, 24 Iowa woody plants, and 20 Pacific coast woody plants, shows a significant correlation between mesophyll organization and vein distribution.

When the tissues of the blade are resolved into two categories—(1) those of horizontal trend with cells closely united laterally (epidermis and spongy mesophyll), and (2) those of vertical elongation with limited lateral contacts (palisade)—the ratio between these two somewhat antagonistic systems is related to vein distribution. Increased amounts of palisade tend to force veins nearer together while larger proportions of spongy mesophyll favor their wider separation.

The working units of the foliage leaf are narrow bands of tissue associated with the minor veins, regardless of their arrangement. For the 66 species surveyed the mean vein separation, or intervascular-interval, was 130 microns, which is twice the conduction distance in the midplane. This suggests that problems of transfer from cell to cell restrict mesophyll to proximity to vascular supply. All tissue arrangements that further or retard conduction between living cells and veins become factors in vein separation.

## POLLEN ANALYSIS OF A BOG IN NORTHERN IDAHO 1

Henry P. Hansen

This study is one of several concerned with postglacial forest succession in the Pacific Northwest as interpreted from pollen analysis. The author eventually expects to have completed similar studies of bogs located within most of the climax formation areas in Washington, Idaho, and parts of Oregon. The postglacial forest succession for the entire region will be correlated from these data, and conclusions drawn as to climatic trends. The bog of this study lies at an elevation of about 2,000 feet, in T. 61 N., R. 5 W., Sect. 34, on the Priest River, Idaho Quadrangle. This region was glaciated by ice of Wisconsin age, which extended as far south as Spokane (Flint, 1937). The bog has been developed in a kettle in a small, outwash-filled valley near Kalispel Creek, a few miles to the west of Priest Lake. The total area of the bog is about fifty acres, with an open lake (Hagen L.) of several acres still in existence near the south end. Near the shore of the lake a floating plant hydrosere exists, characterized chiefly by the yellow pond lily (Nymphaea polysepala). A Sphagnum moss mat surrounds the lake, which supports a heavy growth of cranberry (Vaccinium oxycoccus) and bog laurel (Kalmia polifolia). On the outer edge of the Sphagnum mat is a sharply delimited zone of young western white pine (Pinus monticola), succeeded by zones of spiraea (Spiraea menziesii), sedge (Carex spp.), and alder (Alnus sinuata). The latter grades into the forest on higher adjacent ground.

The depth of the peat in the area of sampling is 12 meters, with a thin layer of volcanic ash at 9 meters. The ash may be correlated with that found in bogs near Spokane (Hansen, 1939), and possibly with that in bogs in the Puget Sound region (Hansen, 1938; Rigg and Richardson, 1938). The lower three meters are composed of gray-brown sedimentary peat which contains a few gastropod shells. The sedimentary peat grades upward into sphagnum peat. Sphagnum moss leaves make their first appearance at 9 meters and gradually increase in abundance. The upper meter consists of shrubby peat, composed of ericaceous shrubs and Sphagnum. Peat samples were taken south of the lake at half meter intervals with a Hiller borer. For study, the peat was deflocculated by boiling in a weak solution of potassium hydrate, washed several times, centri-

Received for publication January 17, 1939.

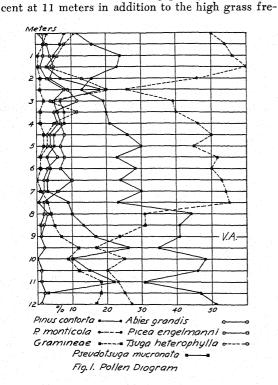

fuged, stained with gentian violet, and mounted in glycerin jelly. From 300 to 500 pollens were identified from each level. There seems to be no difficulty involved in distinguishing the pollens of pine, spruce, and fir in the Pacific Northwest. Identification may readily be based on the total size of the pollen, position of the air sacs on the cell, relative size of the sacs and cell, and the shape of the cell.

Pollens of certain species which are of no significance as indicators of forest succession usually occur in each level. Many of these species grow on or near the bog. The pollens of these species may be present in large numbers, and thus represent a high percentage of the total. In computing percentages for the curves, it seems best to let the pollens of significant species represent 100 per cent. The numbers of non-significant pollens are computed as a percentage of the total significant pollens. By this method, the relative abundance of the non-significant pollens is shown, and the curves of the significant pollens are probably more valid.

FORESTS IN ADJACENT AREAS.—The bog is situated within the Canadian Life zone as defined by Merriam (1898). On Thornwaite's map of the climatic provinces of North America, this area is also designated as having a sub-humid, microthermal climate, with adequate precipitation at all seasons (Thornwaite, 1931). Forest type maps indicate this region as largely covered with a white pine forest type (Larsen, 1930). Although white pine is often the most abundant and may occur in almost pure stands, the climax association is composed of western red cedar (Thuja plicata), western hemlock (Tsuga heterophylla), and lowland white fir (Abies grandis) (Hubermann, 1935). White pine is a subclimax species which persists as a result of fires and lumbering, which destroy the forest and prevents it from reaching its culmination (Larsen, 1929). If undisturbed for a prolonged period, the climax forest assumes the dominant rôle, and white pine persists as older individuals, scattered throughout the stand. On the dryer and exposed sites, Douglas fir (Pseudotsuga mucronata) and western larch (Larix occidentalis) thrive, while western yellow pine (Pinus ponderosa) may frequently be found. The poorer sites are occupied largely by lodgepole pine (Pinus contorta). Subalpine fir (Abies lasiocarpa) and Engelmann spruce (Picea engelmanni) inhabit the cooler and damper sites near the upper edge and above the white pine type. The mean annual precipitation in the area occupied by the hemlock-cedar-white fir association ranges from 27 to 44 inches (Larsen, 1930).

Forest succession.—The pioneer postglacial forests to invade areas adjacent to the bog consisted chiefly of lodgepole and white pines, with percentages of 51 and 27, respectively, in the lowest level (fig. 1). This would seem to indicate an initial cool period of medium dryness. The frequency of 17 per cent for grass at the same level, and of 18 per cent at 11½ and 11 meters indicates its presence in abundance. The sharp increase of Douglas fir to 22 per

cent and the decrease of lodgepole pine to 31 per

quencies may indicate a warmer and perhaps somewhat dryer climate, which is recorded to the 91/2 meter level. This period is probably to be correlated with an early warm and dry period as indicated by pollen analysis of a bog near Spokane (Hansen, 1939). Here there is a heavy influx of grass, chenopods, and composites, marking the extension of the treeless Arid Transition and Upper Sonoran Life zones. This warm and possibly dry period apparently terminated about the time of the deposition of the volcanic ash in both areas. Grass decreases from 9½ meters and maintains low frequencies throughout the rest of the spectrum (fig. 1). Lodgepole pine was likewise a pioneer species in postglacial forest succession near Spokane and in the Puget Sound region (Hansen, 1938).

A period of increasing coolness and moisture is perhaps marked by the increase in both white pine and lodgepole pine from the  $9\frac{1}{2}$  to 8 meter level. At this point lodgepole sharply decreases from 44 to 23 per cent, while white pine increases from 31 to 55 per cent at the  $7\frac{1}{2}$  meter level. This is the first time that white pine shows a higher frequency than the former, and it maintains its dominance to the present time. With the exception of this reversal of dominance, however, both are closely correlated throughout the spectrum (fig. 1).

In general both white and lodgepole pines show gradual decreases from 71/2 to 21/2 meters, at which point they have frequencies of 13 and 26 per cent, respectively, the lowest for both since the deposition of the ash. During this period, Douglas fir, western hemlock, and white fir slowly increase. The latter reaches its highest frequency of 12 per cent at 3 meters, while the former two record 18 and 20 per cent, respectively, at 21/2 meters. This period evidently represents a trend toward a climax development, which was suddenly interrupted at the time represented by the  $2\frac{1}{2}$  meter level, probably by fire. White pine again rapidly increases to 60 per cent at 11/2 meters, while lodgepole pine increases less rapidly. Another trend toward climax development occurs from this point to the surface as indicated by the decrease in white and lodgepole pines and the increase in Douglas fir and hemlock. The appearance of western red cedar pollens at  $3\frac{1}{2}$  meters is to be noted as further evidence of a recent climax trend (table 1). The history of white pine as a subclimax species in postglacial forest succession is similar to that of Douglas fir in the Puget Sound region. Here Douglas fir is subclimax to the cedarhemlock climax, and it likewise has been able to maintain its dominance during postglacial time (Hansen, 1938).

Engelmann spruce maintains frequencies of more than 5 per cent from 7 to 2 meters, while subalpine fir is represented by low frequencies throughout most of the spectrum (table 1). Traces of western yellow pine also occur in many of the levels. Alder, maple, birch, and willow pollens are abundant in the lower levels, but as previously explained, their numbers were not used in computing the percentages of the significant pollens. Larch is conspicuous by its absence, because it is abundant in areas not far removed from the bog. Here it exists in almost pure stands, where repeated fires have prevented other species from entering (Larsen, 1929). It played an important part in early postglacial forest succession in the vicinity of Spokane (Hansen, 1939).

While the climatic interpretation is tentative, it agrees essentially with that indicated by pollen analysis of bogs in the Puget Sound region and near Spokane. The general trend is also somewhat in agreement with that interpreted by some workers in the Middle West. Fuller (1935) believes that the mid-lake records indicate (1) a well marked period of increasing warmth; (2) a long period of maximum warmth; and (3) a poorly emphasized period of decreasing warmth. Von Post (1930) reaches

similar conclusions with respect to European postglacial climatic sequence. Sears (1932) basing his interpretation upon work in Ohio, Iowa, and Canada, concludes that there were several alternating periods of dryness and humidity, with a final warm and humid period. In northern Idaho the initial cool period gave way to one of warmth and desiccation and was succeeded by a period of increasing coolness and moisture, which, when once reached, has persisted to the present time. Forest succession in the Pacific Northwest is perhaps more dependent upon the relative tolerance of the species for shade than upon climatic change. This has probably been true during the latter part of postglacial time.

#### SUMMARY

Pollen analysis of a post-Wisconsin bog in Northern Idaho seems to indicate an initial postglacial forest of lodgepole and white pines, with an abundance of grass, marking a cool and medium dry period.

An abundance of Douglas fir and grass apparently reflects a second warmer and dryer period, which is also evidenced by analysis of a bog near Spokane, Washington.

A third period of increasing coolness and moisture is shown by the rapid increase in white pine to become dominant over lodgepole pine and the rapid decline of Douglas fir and grass.

This period was followed by one marking a trend toward climax development of hemlock, cedar, and white fir; and the decrease in the white pine subclimax. This trend apparently was interrupted, possibly by fire.

A fifth period of white pine increase is followed by a final period of slight decrease for the same species and another climax development trend. Climate probably has remained uniform since the maximum coolness and moisture of the third period was reached.

The interpreted climatic sequence in this region seems to correlate closely with that farther south near Spokane and to some extent with that in the Puget Sound region. The climatic interpretation is tentative until further work in the Pacific Northwest substantiates or refutes the foregoing conclusions.

### NOMENCLATURE PROPOSALS FOR THE 1940 BOTANICAL CONGRESS 1

## F. R. Fosberg

The vast majority of botanists have little concern about the finer and more controversial points of nomenclature. They merely desire that the rules be understandable and definite in application and that they involve as little change in accepted nomenclature as possible. Ordinarily it matters little which way a question is decided, so long as the decision is definite and so worded that it is not necessary to have legal as well as botanical training to be able to interpret it.

Probably no set of rules will ever be drawn up with wording so perfect that no misinterpretations and ambiguities will appear later. These must be eliminated as they appear, in order that the rules may properly serve the purpose of clarifying con-

fusions in plant names.

It would seem better to point out certain inadequacies in the rules before the 1940 congress than to complain about them afterward. Therefore I am presenting here suggestions for discussion upon several articles which have, during the past four years, given trouble.

Nomina Provisoria.—In the first place, the term "nomen provisorium" (of Art. 37 ter. adopted at Amsterdam) should be defined in such a way that at least two botanists will be able to agree upon its meaning. I will leave it to someone who has convictions as to what it should mean to present a motion

on the question.

Proposal to amend Art. 30.—A fertile source of confusion has been the status of the subspecific or varietal epithets applied to the subdivision to which the type of a species belongs—the epithets typica, genuina, originaria, etc., of Recommendation XVIII. Under ordinary circumstances the question is not raised. Those who use these terms customarily treat them exactly as any other epithets of the same rank. Trouble comes only in those cases where an earlier varietal name has been applied to the form represented by the type of a species. Then the question arises as to whether this earlier varietal name should apply or whether it should be superseded by a var. typica or other such name.

Art. 30 says clearly enough that the earliest epithet of the proper rank should be used. No distinction is evident between ordinary epithets and those of the var. typica sort, but this is by no means agreed to by all botanists. At least two prominent American botanists have recently proposed the epithet var. typica when perfectly valid earlier varietal epithets appear in their synonymy (Munz, Bull. Torrey Bot. Club 64: 297, 1937; Fernald, Rhodora 39: 450, 1937). Editors, also, sometimes object to the use of an earlier varietal name to designate the "typical" form if it is based on a different type specimen than that of the species.

It has been explained to me that the expression var. typica is not a scientific epithet but merely a word to designate the typical subdivision of a species. It is maintained that this function is not performed by ordinary subdivisional epithets. It seems to me that any epithet is merely a word to designate a particular group of plants. Our rules are designed to govern the use of these words. There is nothing in the rules which says ordinary subdivisional epithets shall not designate the typical subdivision.

Of methods of dealing with these difficult cases, omitting consideration of those workers who prefer not to distinguish the typical form by any subdivisional epithet, there are at least three that have been used and one other suggested. First, there is that mentioned above, of giving epithets of the var. typica sort preference over all others and exempting them from the principle of priority. A second, which I have seen used lately (St. John and Hosaka, Occ. Pap. Bish. Mus. 14: 119, 1938), is to invoke Art. 60 case (1) and consider that the earlier varietal name, being unknowingly applied to the form containing the type of the species itself, was superfluous when published, therefore illegitimate. The third is to give var. typica exactly the same status as any other varietal name (St. John, Occ. Pap. Bish. Mus. 11, no. 13: 12-13, 1935; Fosberg, Madroño 4: 189-191, 1937), applying strict priority, but, of course, bearing in mind Recommendation XVIII, when creating new names. The fourth method, which has been suggested by Bolle (Notizbl. 13: 524, 1937), is to abolish all such terms as var. typica and simply repeat the specific epithet, with or without the prefix eu-, in all minor categories for the form containing the type.

Any one of these four solutions is perfectly workable. All that is required is a paragraph inserted in the rules designating one of them as the correct pro-

cedure.

The first method mentioned is directly contrary to Art. 30 of the rules as they now stand, as is also the fourth when an epithet of the proper rank is already in existence. In such cases they both violate

the principle of priority.

The second necessitates a very dubious interpretation of what makes a name superfluous when published. Art. 60 case (1) seems at best destined to cause as much confusion as it eliminates, without being applied to cases of this sort. Many botanists will argue that an epithet for the typical subdivision of a species is at any time superfluous.

The third of the above usages, though not innately superior to the others, is the only one that is thoroughly in accord with the rules as they now stand. It is the only one whose adoption will not amount to making an exception to the rules. The objection to having the species and its typical subdivision represented by different type specimens seems ground-

<sup>&</sup>lt;sup>1</sup> Received for publication January 6, 1939.

less; so long as the two types represent the same variety or form, this can cause no confusion, and as soon as they are shown to be different, a new name must be given one of them anyhow. This would naturally be given to the type of the species and would be of the var. typica sort. The proposition of Dr. Bolle (l.c.) for repeating the specific epithet would not be excluded in cases where no name of the proper rank already exists, as his procedure is permitted under the rules as they now stand (Art. 30 and Rec. XVIII).

As it will entail no change in the rules other than to make more definite their application, to provide a basis for discussion the following motion is presented to the section on nomenclature: Article 30 shall be amended by insertion of "Such subdivisional epithets as typica, originaria, genuina, etc., or subdivisional epithets which are repetitions of the specific name are to be treated, nomenclaturally, the same as any other epithets for groups below the

rank of species."

PROPOSAL TO AMEND ART. 36.—Names published in advertisements and nurserymen's catalogs have been the source of much uncertainty, both because of the poor descriptions that often accompany them and because it is sometimes argued that they cannot be considered validly published. An example is the publication of four "new species" of Eranthemum by Wm. Bull in an advertisement in Gardener's Chronicle n. s. 3: 619, 1875. According to a strict interpretation of the rules these would have to be considered as effectively published, but there has been much ambiguity in the use of the names there published. The best way of eliminating the confusion caused by such names seems to be to consider all names published in advertisements ineffectively published. Obviously, if they had been intended as scientific publications, the medium of advertisements would not have been used.

This may be accomplished by adopting the motion here proposed: To amend Article 36 by adding "Seedsmen's and nurserymen's catalogs or other obvious commercial advertisements, whether in a periodical or privately distributed, are not to be considered effective means of publication, even though the names used in them are accompanied by descrip-

tions."

Proposal to amend Art. 60.—When a name or epithet previously invalidly published is validated by a subsequent author but ascribed to the author who published it first, the question sometimes comes up as to whether the application of the name is to be determined by the intention of the original author, if determinable, or by the sense in which the name is used by the author who validates it. Thus, if Eranthemum atropurpureum Bull, in Gard. Chron. 18. 3: 619, 1875, is considered invalid, either as a nomen subnudum or because published in an advertisement, Hooker's use of the name in Bot. Mag. t. 7839, 1902, with an excellent description, must be regarded as a validation of it, as Hooker refers to Bull as the author of the name. Radlkofer in Sitzb.

Math.-Phys. Cl. Acad. Wiss. Muench. 13: 286, 1884, transferred the species to *Pseuderanthemum*. Bailey in Gentes Herb. 1: 130, 1923, considered that Hooker had described a different plant from that which Bull had in mind (on the basis of a specimen deposited at Kew by Bull many years after the publication of the name and by no means necessarily the same plant as that described in 1875). He therefore retained the name *Pseuderanthemum atropurpureum* for Bull's plant and renamed Hooker's plant *Ps. kewense*.

Radlkofer's combination is, of course, invalid, as the only reference is to Bull's nomen subnudum. Bailey (l.c.) remade the combination, specifically stating that it was for Bull's plant, not Hooker's. However, in view of Article B54, as adopted at the Amsterdam congress (Proc. Int. Bot. Congr. Amsterdam 1: 354, 1936), it seems that Bailey's combination should be applied to Hooker's plant. Ps. kewense Bailey is, in any event, illegitimate; it was superfluous when published. Bailey should have used Hooker's name for it and renamed Bull's plant. Bull's plant is without a name.

To avoid such situations in the future, the following motion is presented: To Article 60 add: "The application of a name is to be determined by the sense in which it is used in its first valid publication. Previous invalid publications do not affect it excepting only when they are useful in doubtful cases as a help in determining the application in the

earliest valid publication."

Two generic names proposed for conserva-TION.—The names Artocarpus Forst., Char. Gen. 101, 1776, and Inocarpus Forst., Char. Gen. 66, 1776, are hereby proposed to the Special Committee for Phanerogamae and Pteridophyta for inclusion in the list of Nomina Generica Conservanda. Both are antedated by names legitimately published three years earlier by Parkinson in "A Journal of a Voyage to the South Seas in His Majesty's Ship, The Endeavor," 1773. The earlier name for Artocarpus Forst. is Sitodium Parkinson, l.c. p. 45, and that for Inocarpus Forst. is Aniotum Parkinson, l.c. p. 39. Both Parkinson names are published with combined generico-specific descriptions (see Art. 43), with binomials and in a work in which binomials are consistently used. To any one familiar with the Polynesian flora there can be no ambiguity as to the application of the names, and the descriptions are as complete as those in many accepted works of the time. Taken with the supplementary data available (see Merrill, in Jour. Arnold Arboretum 19: 301-2, 1938), they are positively identifiable.

Following is a concise statement of the cases for conservation of these two genera, for the use of the committee. Though Article 21, note 1, of the rules requires a statement of the cases both for and against conservation of proposed names, there seems to be no case whatever against conservation of these names, excepting perhaps the small size of the genus

Inocarpus.

Artocarpus versus Sitodium.—Artocarpus (Moraceae) is a genus of about 40 species of tropical Asia to Polynesia and cultivated in all tropical regions. Its conservation over Sitodium seems warranted by the facts stated below.

The genus includes several well known economic species, such as the common bread-fruit and the jak-fruit, and the name is in common use by horticulturists, travelers, and ethnologists, as well as by botanists. A change would cause great confusion to these people.

The name Artocarpus has been in continuous use since 1776, while Sitodium has been used only by Gaertner in one publication since it was first published.

Index Londinensis lists 192 plates under the name Artocarpus against 1 under Sitodium.

Important general works such as DC. Prodromus 15 (1): 264, 1864; Benth. & Hook., Gen. Pl. III, 1: 376, 1880; Engl. & Pr., Die Nat. Pflanzenf. Ed. I, III, 1: 82, 1889; such important regional floras as Trimen's Handb. Fl. Ceyl. 4: 98, 1898; Miquel, Fl. Ned. Ind. 1 (2): 284, 1859; Merrill, Enum. Phil. Fl. Pl. 2: 40, 1923; Seemann, Fl. Vit. 255, 1873; Rock, Ind. Tr. Haw. Is. 115, 1913; such important horticultural works as Bailey, Stand. Cycl. Hort. 1: 401, 1928; and such important morphological works as Janssonius, Mikrogr. 6: 241, 1936, all adopt Artocarpus.

Inocarpus versus Aniotum.—Inocarpus (Leguminosae) is a genus of perhaps three species, of tropical Asia to Polynesia and Guiana (?) and widely planted as a food plant in the Pacific islands and Asia. Its conservation over Aniotum seems warranted by the facts stated below.

The principal species of the genus is an important economic plant in tropical regions, as well as a morphological curiosity, anomalous in its family, and the name is in common use by horticulturists and ethnologists, as well as by botanists. A change would cause great confusion to these people.

The name *Inocarpus* has been in continuous use since 1776, while *Aniotum* has been used only by Gaertner in one publication since it was first published.

Index Londinensis lists 10 plates under the name Inocarpus and none under Aniotum.

Important general works such as DC., Prodromus 17: 284, 1873; Benth. & Hook., Gen. Pl. 1: 552, 1867; Engl. & Pr., Die Nat. Pflanzenf. Ed. I, III, 3: 348, 1894; such important regional floras as Miquel, Fl. Ned. Ind. 1 (1): 887, 1855; Merrill, Enum. Phil. Fl. Pl. 2: 302, 1923; Brown, B. P. Bish. Mus. Bull. 130: 118, 1935; and such important morphological works as Janssonius, Mikrogr. 3: 82, 1918, all adopt *Inocarpus*.

## RESPONSE OF LETTUCE SEEDLINGS TO 7600A RADIATION 1

Lewis H. Flint and Charles F. Moreland

In studying the effect of spectral light upon the germination of light-sensitive lettuce<sup>2</sup> seed, Flint and McAlister (1935) found that a band of radiation at about 7600A inhibited the germination. Numerous researches had previously given results in which unfavorable effects had been attributed to general near infra-red radiation, but in these experiments the range of the effective radiation was fairly well defined.

In studying the phoeolic movements of Mimosa pudica in relation to intensity and wave length, Burkholder and Pratt (1934) also found near infrared radiation of about the same critical wave length maximally effective. The two sets of data were graphically brought together for comparison by Burkholder in his survey of light in relation to plant growth (1936). The order of agreement indicated by this comparison appeared sufficient to suggest that the near infra-red radiation at 7600A might have a more general influence on plants. The experiments here reported were carried out in line with this suggestion.

Метнорз.—In these experiments light-sensitive lettuce seeds were placed on moist filter paper in

<sup>1</sup> Received for publication January 16, 1939.

<sup>2</sup> Lactuca sativa L.

Petri plates and exposed to red light at 20°C. for 48 hours. At this time uniformly-germinated seedlings were selected and arranged on moist cotton or filter paper in small moist chambers for exposure to 7600A radiation. In the first series of trials the 7600A radiation was introduced at a horizontal incidence in a dark chamber, the seedlings outside the beam thus being in total darkness and constituting the control or check plants. In the second series of trials the 7600A radiation was introduced into the dark chamber at a vertical incidence, the plants outside the beam again constituting the checks. Several variations in the manner of exposure were included with a view to reducing chance as a factor in the indicated response. A trial with radiation at 6500A and another with radiation at 8500A were included to indicate something of the specificity of the response to 7600A radiation.

In these experiments a Mazda 1000-lumen street lamp was used as the light source for the continuous radiation. Suitable combinations of intensity and monochromacity of radiation were obtained with a reflecting monochromator. The intensity was measured with a vacuum thermocouple and galvanometer. There was no control of temperature within the exposure chamber, and this would sometimes vary sev-

eral degrees during the course of an experiment. However, no differences in temperature were detectable in the treated and check areas occupied by the seedlings.

RESULTS.—In the first series of trials with lettuce seedlings subjected to 7600A radiation at horizontal incidence, no bending was obtained. Follow-up trials with maize coleoptiles also gave no bending. As a further check, the lettuce seedlings were exposed to radiation at 4800A, and pronounced bending took place rapidly. It was thereupon concluded that there was no phototropic response to 7600A radiation.

In the second series of trials the lettuce seedlings were subjected to 7600A radiation at vertical incidence. The first experiments of this series gave the results brought together in table 1.

It was considered that several objections might be made to the arrangements indicated in table 1. The seedlings exposed to the 7600A radiation were in the center of a disc and might therefore be exposed to inhibiting substances exuded from the surrounding plants. To overcome this objection an arrangement was chosen which permitted a random selection of the group of seedlings exposed to the radiation. The seedlings were situated about seven feet from the ordinary S-type Mazda burning at 12 volts, and, as previously stated, no temperature differences between the exposed area and that adjacent to it could be detected with a thermometer. Yet to make certain that the effect of the 7600A radiation was not simply due to a drying out of the area, some experiments were included in which water was left standing above the moist filter papers in the Petri

dishes. The same stunting effect was obtained under these conditions. Another objection to the experiments as given in table 1 is that the stunting effect may be only a part of a more general influence extending into the infra-red. To test this possibility, some experiments were carried out with radiation at 8500A. No stunting effect whatever was obtained with this radiation.

Yet another objection to the experiments of table 1 is that the stunting effect may be associated with assimilation. The assimilation curve of Hoover (1937) indicated that the long wave length limit of radiation promulgating assimilation was about 7400A. This point was well within the range involved in the treatments at 7600A. To satisfy this objection, the slit-widths of the monochromator were so reduced as to produce an emergent beam devoid of any radiation effecting assimilation. When trials with this beam still gave stunting effects, an additional trial was run with increased energy at 6500A—the maximum of Hoover's assimilation curve. The results of these supplementary experiments have been brought together in table 2.

It will be noted from the results given in table 2 that while the stunting effect was less marked at the reduced energy, there was no stunting effect either at 6500A, the point of maximum assimilation in Hoover's curve, or at 8500A, a point further into the infra-red range. There remains the possibility that the stunting effect of 7600A radiation might be nullified when coupled with 6500A radiation; but since the latter did not influence elongation when compared with darkness, although greening took place, this possibility appears rather remote.

The general characteristics of the radiations used in these experiments, together with a portion of Hoover's curve of assimilation, are indicated in the accompanying graph (fig. 1).

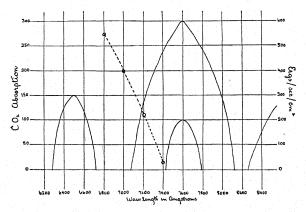

Fig. 1. Characteristics of radiations used in experiments with lettuce seedlings. Solid line: radiations, plotted against scale at right; broken line: portion of assimilation curve of Hoover, plotted against scale at left.

The stunting effect of the 7600A radiation as obtained in these experiments is indicated in the accompanying photograph (fig. 2).

Discussion.—The 7600A radiation, which was found to inhibit the germination of light-sensitive lettuce seed, also appears to stunt the development of the seedlings. This stunting effect does not appear to be associated with assimilation, nor with temperature. The extent to which this radiation may

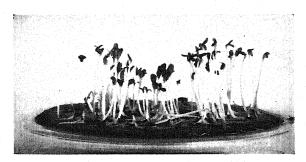

Fig. 2. Stunting effect of 7600A radiation on lettuce seedlings. Plants in center exposed to radiation.

have a similar effect upon other plant material is not known.

In accordance with a long-established principle the material responding to 7600A radiation might be expected to contain pigment absorbing this radiation. Up to the present time no satisfactory data indicating such an absorption have been obtained. It may be noted that in figure 2 the exposed seedlings have a somewhat darker appearance than the controls. This darker appearance was less noticeable to the eye. There has never been obtained any greening in plants exposed to the 7600A radiation.

Conclusions.—Radiation at 7600A stunted the the growth of lettuce seedlings. The effect was not associated with assimilation nor with temperature. Radiation at 6500A and at 8500A had no stunting effect.

Radiation at 7600A incited no phototropic response in lettuce seedlings.

## INFLUENCE OF LIGHT ON THE LENGTH OF THE CONIDIA IN CERTAIN SPECIES OF FUSARIUM <sup>1</sup>

L. L. Harter

A CONSIDERABLE amount of literature has accumulated on the influence of light and radiation on fungi, which for the most part deals with a variety of physiological processes but in few, if in any case, with the direct influence of light and dark periods on the size of the spores, as shown by actual measurements. Appel and Wollenweber (1910) found that when Fusarium cultures were grown in the dark, the conidia were often abnormal in form and variously septated. Ramsey and Bailey (1930) found that a strain of Fusarium coeruleum (Lib.) Sacc. that had never produced conidia was induced to do so when a culture was exposed to ultra-violet radiation and that under the same treatment a culture of Fusarium argillaceum (Fr.) Sacc. produced only chlamydospores. Stevens (1928, 1931), working with a different group of fungi, showed that radiation from a quartz-mercury vapor lamp induced the development of perithecia in cultures of Glomorella cingulata (Atk.) S. and S., Colletotrichum lagenarium (Pass.) Ell. and a species of Coniothyrium. Smith (1935) also found that short exposures of cultures to ultra-violet radiation caused a marked stimulation in spore production. Ramsey and Bailey (1930) as well as Smith demonstrated that the increase in spore production did not seem to be correlated with any inhibition of the vegetative growth. Of interest also are the results of Brown (1925) to the effect that Monilia fructigena (Pers.) Schr. in general showed a tendency to sporulate in the light, and those of Coons and Levin (1920) that pycnidia formation was stimulated in different genera of the Sphaeropsidales by the action of two 100-watt nitrogen filled incandescent lamps. As an explanation of their results, Coons and Levin suggested that the effect of the light on the mycelium of Plenodomus fuscomaculans (Sacc.) Coons served as an oxidizing force, unlocking the reserves of cellular food, thus furnishing the energy for the fruiting processes.

It is evident from the literature already cited that previous studies on the effect of light on fungi have dealt mostly with its influence on color production, vegetative growth, and spore population rather than

on the actual size of the conidia.

The problem.—The data to be reported in this paper are the results of the writer's efforts to explain in part at least why he has been unable in many cases to identify correctly certain species of Fusarium with which he worked or which came under his observation. The investigations of Wollenweber (1931) and Wollenweber and Reinking (1935) give complete descriptions of the different species of Fusarium with numerous measurements of the length and width of the macroconidia and microconidia, size of the chlamydospores, as well as color reactions on different culture media and other

<sup>1</sup> Received for publication January 30, 1939.

characteristics of the organisms that might enable the student to separate one species from a closely related one. In spite of these details, it is often difficult, if not impossible, by any means of manipulation of the culture to obtain a morphological agreement with the description of a given species. In fact a spore or clonal transfer from a type culture does not always give a culture whose spores or other characteristics agree with the original. Differences in spore size as great as that between two distinct species sometimes result from such a transfer. Other difficulties are frequently encountered in pathological or mycological work where species of Fusarium are involved. Different isolates from the same host when collected either from the same or a different locality do not always agree morphologically with the original description of the species. These difficulties are further increased when species, varieties, or forms are separated on the basis of differences of a few microns in the average length of the conidia. The difficulties experienced by the writer have also been experienced by many other investigators who have attempted to identify species by using the recognized standards of morphological relationship. Many of the difficulties of the classification of species of Fusarium as formulated by a Fusarium conference in Madison, Wisconsin, in 1924 have been concisely stated by Nelson, Coons, and Cochran (1937), who feel that morphological characters alone are not sufficient to enable anyone but a specialist on this genus to segregate species.

The lack of any uniform methods of handling cultures has doubtless contributed something to the confusion. Little has been attempted in the way of studying the effects of various agencies such as light, temperature, etc., on the size and shape of the conidia, although it has been recognized that they influence the reproductive behavior of the organism.

The writer believes it can be shown that photoperiodism influences the length of the conidia of certain species of Fusarium independently of other agencies and that the mean length of spores taken from different culture tubes derived from the same clonal line differs greatly when the organisms are reared under otherwise identical conditions. It is believed that these investigations will explain, in part at least, why so much difficulty, confusion, and incorrect identification have been experienced in this important group of fungi.

Species of Fusarium investigates.—Three species of Fusarium have been employed—namely, F. coeruleum, F. Martii var. pisi Jones, and F. bulbigenum var. batatas Wollenw. These three species were selected principally because they had continued to produce pionnotes and sporodochia for several years on several different culture media—a prerequi-

site in work of this kind. Fusarium bulbigenum var. batatas, however, did not maintain its ability to form sporodochia to quite the same degree as the other two species, especially on certain culture media. For that reason the data with respect to this species are not so complete as for F. coeruleum and F. martii var. pisi.

Fusarium coeruleum (I.K. 6721)<sup>2</sup> was isolated from the roots of peas in Colorado by W. J. Zaumeyer in 1932. It forms a copious, dark indigo blue pionnotes on cooked potato, stringbeans, 2 per cent potato-dextrose agar, and most of the culture media in common use, and can be maintained in such a state of growth without difficulty. It is the cause of a root rot of peas (Harter, 1938). Because of the constancy in its growth behavior, it has been admirably suited for the study of the influence of light and dark on the length of the spore.

Fusarium martii var. pisi (I.K. 6865a), the cause of pea root rot, is a descendant from the original culture made by F. R. Jones, who first studied the disease and described the organism. It produced green pionnotes or sporodochia on cooked potatoes, potato-dextrose agar, bean pods, and certain other media. It does not produce the copious pionnotes produced by F. coeruleum and is somewhat more difficult to maintain in "high culture." By frequent transfers to suitable media, it has been maintained in a condition satisfactory for the problem under investigation.

Fusarium bulbigenum var. batatas (I.K. 7313c), a representative of the section Elegans, is a vascular parasite and the cause of the wilt or stem rot of sweet potato (Harter and Field, 1914). It forms a copious pionnotes on cornmeal agar, 2 per cent potato-dextrose agar, and other media when first isolated, but later the spore masses were reduced to well developed sporodochia. This species was more difficult to maintain in high culture than either of the two others, or other species of the section Martiella.

EXPERIMENTAL PROCEDURE.—Preparatory to starting the investigations, each organism was "purelined" by picking a single conidium from an agarplate colony and transferring it to another agar plate or to some suitable culture medium in a test tube. These lines were used as a source of all subsequent transfers. Stock cultures were maintained on a medium found to be the best for the production of pionnotes and were grown in the light, generally on the ledge of a north window, in a room where the temperature varied from about 15°C. to 24°C. during the winter months.

All spore measurements were made from cultures grown in test tubes. All agars were slanted and the inoculum smeared the length of the slant. When cooked potatoes, stringbeans, or similar media were inoculated, the inoculum was spread as much as possible over the surface in order to obtain as uniform a distribution of the spores as possible. In all trials

<sup>2</sup> Isolation Key Number 6721 carried in the files of L. L. Harter. care was exercised to select test tubes of uniform diameter.

The culture media were inoculated as follows: about the amount of spore material that would fill a 1 mm. platinum loop was transferred from a stock culture tube to 2 cc. of sterile water in a test tube. The spore suspension was then shaken vigorously to insure a uniform dispersion of the conidia in the water. From this spore suspension, a single transfer was made to the tubes to be used for exposure to the different light values by the use of a number 24 B & S platinum wire.

Inasmuch as these experiments have to do with the influence of various durations of light and dark on the length of the conidia, the methods of preparation and manner of exposure will be described in considerable detail. Each tube to be kept in the dark for the entire length of the experiment or for selected intervals was wrapped with six thicknesses of black paper such as is used to wrap unexposed photographic plates or films. The paper extended from the upper end of the test tube to about two inches below it. The portion of the paper that extended below the tube was folded over to shut off any light from the bottom. The paper did not extend above the tube or over the cotton plug so that there was the same opportunity for the exchange of air as in the unwrapped tubes. A small amount of light may have entered the tube through the cotton plug, but it is believed to be so small as to be negligible. When the tubes were exposed to solar irradiation, the wrapper was removed for the desired length of time and replaced at the end of the light exposure period.

The investigations were divided into two parts: (1) those in which solar irradiation was used as a source of light; (2) those in which artificial light was employed. In the latter case the cultures were kept in incubators with light excluded, except as it was supplied artificially in a known intensity and for a selected duration of time.

The incubators were well insulated boxes  $3 \times 2 \times 2.5$  feet in size and black inside. They were located inside an insulated, practically light-proof refrigeration room maintained at a temperature of  $9-10^{\circ}$ C. The refrigeration room and the incubators were thermostatically controlled. Fans were used in the refrigeration room and in the incubators to keep the air in constant motion. The open wire crates used to hold the cultures were placed on a wire shelf about 1 foot above the incubator floor, thereby providing for free circulation of the air around the tubes.

Two-hundred-watt Mazda lamps hung outside the boxes 26 inches from the cultures were the only source of illumination. The duration of the illumination was regulated to suit the experiments. The length of the light and dark periods will be shown as the results of the various experiments are presented.

In those experiments conducted in the laboratory the cultures exposed to the light of a north window were subjected to temperatures varying from about 15° to 24°C. A temperature of 25°C. was employed for most of the experiments where the cultures were exposed to artificial illumination, since a series of experiments with the different species conducted at temperatures of 14°, 18°, 22°, 25°, and 27.5°C. had shown that those grown at 25°C. were, everything considered, equal to if not superior to those grown at the other temperatures. At 27.5°C. the cultures and the conidia were not quite normal, showing that the temperature was probably a little too high. Those grown at 14°, 18°, and 22°C. were very similar in general appearance to those grown at 25°C., but the growth was correspondingly slower at the lower temperatures. Everything else being equal, the temperature giving the most rapid normal development was preferred, and that temperature was 25°C. Pionnotes developed 1 to 2 days later at 22°C. than at 25°C., 4 or 5 days later at 18°C., and about 8 days later at 14°C. The attainment of the reproductive stage in the growth cycle of the different species in the shortest time possible was a matter of considerable importance.

Several tubes of media were inoculated at one time with each organism for each type and length of exposure. Growth was evident in the three species in two days. Pionnotes were forming in cultures of Fusarium coeruleum in 4 days, in F. martii pisi in about 6 days, and in F. bulbigenum var. batatas several days later. In spite of the fact that the spores of F. coeruleum appeared to be fully developed and in every way normal in 10 days, no measurements were made from cultures less than 21 days old. A

correspondingly longer time was allowed for the two slower-growing species.

After a careful consideration of several methods. it was decided to measure the length of 100 3-septate spores chosen at random from each of several culture tubes. A spore suspension was made in water on a glass slide and then diluted to a point where only two or three conidia could be observed in one field of the microscope at the combination of oculars and objectives used in making the measurements. When the desired spore dilution was reached, a cover glass was put on the mount and sealed around the edges with paraffin to hold the spores in place and prevent the water from evaporating. With such a preparation, two or three hours were available for making measurements before the conidia began to germinate. It is believed that if a thin distribution of spores is made on a slide, a reliable sample can be obtained by measuring each 3-septate spore as it comes into the field of the microscope. The method was adopted of starting at one side of the preparation, moving the slide in only one direction and measuring every 3-septate spore that came entirely into view.

EXPERIMENTAL RESULTS.—The spore measurements are recorded in microns. It was believed that a better impression of spore size could be obtained by measuring 100 spores from each culture and recording the number that fell into each micron class, rather than by recording only the maximum, minimum, and average, as most workers with Fusarium have been accustomed to do. The data shown in the several tables are the results of measurements made

from at least two and mostly from five, six, and seven tubes.

Solar irradiation.—The cultures exposed to solar irradiation at room temperature were placed on the ledge of a north window and consequently were subjected to the changes of temperature and light intensity that would naturally occur from time to time. Black paper was used to wrap the culture tubes from which the light was to be excluded for a part or all of the growth period. While the light intensity and temperature were not controlled except in a general way, the cultures were otherwise identical in every respect except that one set was exposed to light and the other wrapped in black paper. Notwithstanding the fact that conditions surrounding the cultures were not accurately controlled, the effect of the different periods of exposure is so striking as to leave little doubt that light exercises a profound influence on the septation and size of the conidia (tables 1 to 3).

The data shown in tables 1 to 3 are the results of exposure of three different species of Fusarium to daylight for different durations of time. Three series were run at one time. One was exposed constantly to all the available daylight, one from 9:00 a.m. to 12:00 noon daily, and one was wrapped in black paper to exclude the light. An examination of these figures shows a consistent trend so far as the length of 3-septate spores is concerned, irrespective of the medium on which the organisms were grown. The greatest mean length of conidia occurred in cultures exposed to the maximum amount of avail-

able daylight under the conditions of these experiments. The conidia next longest in mean length were obtained from cultures exposed to daylight daily from 9:00 a.m. to noon, and the shortest were in the culture tubes wrapped with black paper. The mean length of 400 conidia of Fusarium bulbigenum var. batatas grown on cornmeal agar in daylight and in the dark was 38.7 and 31.6 microns, respectively (table 1). Less significant differences were obtained when identical cultures were grown on green bean pods and on 2 per cent potato-dextrose agar. The difference between the mean length of the conidia of cultures grown in maximum daylight and of those exposed to daylight for 3 hours daily is not so striking as it is between daylight-grown cultures and cultures grown in the dark, but nevertheless is impor-

Equal or even greater differences in the mean length of the conidia are shown in the case of Fusarium coeruleum (table 2) grown on 2 per cent potato-dextrose agar, the length of the spores grown in daylight and in the dark being 42.1 and 30.8 microns, respectively. Variations almost as great occur when this organism is grown on cornmeal agar and cooked potatoes. Fusarium martii var. pisi (table 3), regardless of the culture media used, also showed a decrease in the length of the conidia more or less inversely proportional to the amount of daylight to which the cultures were exposed.

ARTIFICIAL IRRADIATION.—The data shown in tables 4 and 5 were obtained from cultures grown in an incubator with a temperature of 25°C. In all

cases the light was derived from a 200-watt filament Mazda lamp 26 inches distant from the culture tube.

In general the results in an incubator where both the temperature and illumination were controlled were almost identical with those obtained in a laboratory room in which there was no accurate control of either temperature or light intensity. A consideration of some of these data suggested that a similar stimulation of fructification and increase in the length of the spore might be induced by irradiating the culture for only a part of the time following inoculation. With this thought in mind, experiments (table 4) were conducted in which some of the cultures were irradiated for 24-hour periods daily. while others were kept continuously in the dark. In another series (table 5) the cultures were irradiated two and four days immediately following inoculation, after which the light was excluded (dark) for the remainder of the incubation period. In other experiments (table 5) the cultures were kept in the dark for a definite period of time immediately following inoculation, after which they were exposed to continuous light during the last few days of the growth period. Concomitantly with the above experiments, another set of cultures (table 5) was subjected from the start to alternate light and dark periods of 12 hours each in comparison with a similar set of cultures kept continuously in the dark from the beginning.

The effect of artificial illumination in increasing the mean length of the conidia of three species of Fusarium has been fully established by the results shown in table 4. In the solar irradiation experiments (tables 1 to 3) it was found that the conidia of cultures exposed for 3 hours daily had a longer mean length than those of cultures from which the light had been entirely excluded, but these data gave no indication with respect to the period in the life cycle of the fungus when illumination was most effective. When cultures of Fusarium coeruleum that were kept in the dark for the first two days and then artificially irradiated for the remainder of their growth period are compared with cultures irradiated from the beginning (table 5), the results on 2 per cent potato-dextrose agar show a mean length of 38.3 and 37.3 microns, respectively, and on cooked potato a mean length of 36.4 and 35.9, respectively. It appears from these results that darkness during the first two days, when growth is beginning and is mostly of a vegetative nature, has little influence on the length of the conidia. If on the other hand, cultures on 2 per cent potato-dextrose agar were kept in the dark for the first four days and thereafter irradiated, the mean length of the conidia in comparison with similar cultures exposed to light for the first four days and then wrapped in black paper for the remainder of the growth period were 29.9 and 39.7 microns, respectively (table 5). When exposed to the light during the entire period, the mean spore-length was 39.4 microns, from which it appears that if light is employed during the first four days, maximum spore size is obtained. On the

other hand if light is excluded during the first four days of the growth cycle and then restored for the remainder of the time, the mean length of the conidia is practically the same as in cultures grown during the entire period in darkness, that is, 29.9

and 30.2, respectively (table 5).

Artificial light of the kind and intensity used in these experiments seems to be a very good substitute for daylight. All the species tested behaved in about the same way as when daylight was the source of irradiation, in that the mean spore length was greatest when the cultures were exposed to illumination and shortest when the light was excluded by wrapping the culture in black paper.

Discussion.—The several tables show that the 3-septate conidia of three species of Fusarium attain a greater mean length when the cultures are exposed to either daylight or to artificial irradiation than when they are kept in the dark, but otherwise under identical conditions. Spore length has been used as one of the morphological characters in the delimitation of the different species of Fusarium, and inasmuch as light influences the size of the conidia perhaps more than does the composition of the substratum or the temperature at which the culture is grown, it appears that much of the failure to identify properly some of the species is due in part at least to the influence of light.

In any taxonomic study of species of Fusarium, the ideals sought seem to be, among other things: (1) to establish constancy and uniformity of growth behavior; (2) to obtain copious spore masses in the form of sporodochia or pionnotes, in those species where sporodochia or pionnotes are produced; (3) to obtain maximum size of macroconidia; (4) to secure the largest possible number of septations of the macroconidia. The microconidia and chlamydospores also have characters of taxonomic importance. If the above hypotheses are accepted, any cultural manipulation or external influence such as light or temperature that affects the size or other morphological characters of the conidia must be carefully considered in the identification of the different species. In table 1, Fusarium bulbigenum var. batatas grown on cornmeal agar in the light and in the dark produced spores of a mean length of 38.7 and 31.6 microns, respectively, a difference of 7.1 microns. On green bean pods, in the light and in the dark, the same species produced 3-septate macroconidia of 36.7 and 32.0 microns, respectively, or a difference of 4.7 microns. Wollenweber and Reinking (1935) in the subsection "Constrictum" have separated F. bulbigenum var. batatas and F. bulbigenum var. lycopersici by differences of 1 micron in length and 0.1 to 0.2 microns in diameter, together with slight differences in cultural characters. Fusarium bulbigenum var. tracheiphilum and F. bulbigenum var. blasticola have been separated into two species on the basis of a difference of 2.0 microns in length and of 0.3 microns in the diameter of the 3-septate conidia. There is little doubt that if the longer-spored species were grown in the dark even

for as short a time as 4 days, and the shorter one in the light, the relative lengths of the two species would be reversed and would show far greater differences than those given by Wollenweber and Reinking (1935, p. 107). Other species of this subsection and other subsections of the section Elegans are delimited by equally small differences in the size of the conidia. In many cases such differences are less than would be found in two cultures grown under identical conditions.

The data (table 2) obtained with Fusarium coeruleum grown on different media in the light and dark at room temperature show differences in mean spore length of the 3-septate conidia as follows: cornmeal agar, 8.4 microns; cooked green bean pods, 12.7 microns; 2 per cent potato-dextrose agar, 11.1 microns; cooked potato, 6.1 microns. By the standards employed by Wollenweber and Reinking, and others, these variations probably would be more than enough to justify the creation of a new species irrespective of any other characteristic differences. Such differences are further illustrated by reference to table 3, which shows that F. martii var. pisi follows the same general trend as F. coeruleum on the different culture media. The differences in mean spore-length between cultures grown in the light and those grown in the dark far exceed the differences that are employed to delimit a number of the species of the section Martiella according to the scheme of classification already cited. A study of the data contained in tables 4 and 5 will show that a similar trend is followed by all three species.

That the kind of culture medium used influences the size of the conidia has been demonstrated by various investigators. Sherbakoff (1915) describes a number of species of Fusarium in which spore measurements on different culture media are recorded. The extreme dimensions and average length and width were found to vary according to the substratum. Jones (1923) first studied and described F. martii var. pisi, and his published account of the root rot caused by it records the results of his spore measurements on three different culture media. His results show only an inconsequential variation in average size but a somewhat greater variation in maxima and minima. It is interesting in this connection to note that while Jones and the present writer used one culture medium (2 per cent potatodextrose agar) in common, there was no close agreement in the average length of the 3-septate conidia, which shows that two investigators working with a species of Fusarium of the same line may obtain measurements greater than those that exist between recognized species.

While these investigations were concerned mostly with the influence of light on the length of the conidia, certain physiological characteristics of the organisms were manifest throughout. They produced copious pionnotes on all the culture media in the light and to a lesser extent in the dark. They were all consistent in that the amount of pionnotes was less in the dark and first appeared about two days later than in the light. Under the conditions of these experiments, the mycelial or vegetative growth developed more abundantly in the dark (fig. 1) and seemingly at the expense of fructification. In all cases the 1-celled conidia were more numerous when the cultures were grown in the dark than when they were grown in the light. The 0-, 1-, and 2-septate conidia predominated over the 3-septate conidia as much as 4 or 5 to 1 in the dark, and in some cultures it was difficult to find enough 3-septate conidia for a sampling, while in others there were none. This kind of behavior in the dark was so consistent in all the cultures as to leave no doubt of the definite influence exercised by the light rays emanating either from the sun or from an electric lamp. These data cannot be without significance.

There are probably still other good reasons why workers with species of Fusarium find it difficult to identify them. It is not possible in many cases to determine from a publication whether the cultures were grown partly or entirely in the dark, in subdued light, or in strong light. The temperature or temperatures at which they were grown and what culture media were used is frequently not given. One of the conclusions to be drawn from these investigations is that there should be some standardization of methods of study. The nearest approach to anything resembling directions or methods of procedure is contained in a short account by Wollenweber, Sherbakoff, Reinking, Johann and Bailey (1925) on the production of the norm. Their directions are not specific and leave much to be desired. Most of the discussion centers about the culture media and certain suggestions as to the kind to be used. It is recommended that consideration be given to temperature, humidity and light, but here again nothing is said specifically as to the nature of the consideration to be given. Inferentially it is hinted that light is important only to the extent that color production is usually attributed to its influence.

The influence of light has not received the same attention with reference to the development of fungi that it has for the higher plants, because of the fact that light is absolutely necessary to chlorophyllbearing plants, but not indispensable in the life of fungi. The Fusaria will survive when grown in very dark situations. While light perhaps is not indispensable to the existence of fungi, investigations besides those previously described in this paper have shown that it has a significant influence. With quite a different group of fungi, Yarwood (1937) demonstrated that the sporulation of the downy mildews of hop, onion, grape, and lettuce was more luxuriant at night or under dark conditions than in the light. Similar observations were made by Oltarzhevskii (1935) and by Arens (1929), but contrary results were obtained by Melhus, Van Haltern, and Bliss (1928), Weston (1924) and Hiura (1935) working with different parasites, from which situation it is seen that there is no general agreement in the behavior of the different organisms as regards sporulation, and that no general and sweeping conclusions can be drawn for all fungi from the results obtained by a study of a few species. Each organism must be studied separately.

These experiments were designed to determine if light influences the length of the conidia sufficiently to be significant from both the statistical and the taxonomic points of view. The size of the conidia has almost universally been employed in classifying or separating closely related species with each investigator largely deciding for himself if the differences in their size are important and assigning the organism to a particular species according to his own judgment.

The wide difference in mean spore-length of a single species, the cultures of which were grown under identical conditions except with respect to light, the writer believes would generally be admitted to be sufficiently great to justify the creation of a new species. As might be expected statistically, significant differences of easily measurable and recognizable magnitudes are found in many of the individual groups, which indicate that mathematical calculations of significant differences may have a place in the taxonomic study of certain fungi. To be useful, however, the methods of culture manipulation should be standardized.

It is interesting to note that the different light and other cultural conditions, although markedly affecting mean spore length, had but little effect on the coefficient of variability.3 In most instances, in these studies, the C.V. of a single measurement was about 10 per cent of the mean, but varied from extremes of 8 up to 12 per cent. Assuming a C.V. of 10 per cent, the SEm of 100 measurements at random will be 1 per cent of the mean. Among these populations a minimum of about 100 measurements of each must be made to discover significant differences as small as 1 micron.

Another factor to be taken into consideration where species of the genus Fusarium are separated on the basis of small differences in spore size is the variation among different workers. In order to determine the variation in spore measurements due to the individual, a test was conducted with nine experienced investigators familiar with the technique of measuring conidia. A thin sowing of conidia of a species of Fusarium was prepared on a glass slide in a very weak solution of lactic acid, and after removing the excess liquid, the cover glass was sealed around the edge with paraffin to prevent evaporation. The use of lactic acid extended the time the preparation could be safely used before any plasmolysis or other changes in the conidia took place. Each participant was instructed to measure the length of 100 3-septate conidia to the nearest line on the eyepiece micrometer. The measurements were made consecutively.

<sup>3</sup> Grateful acknowledgment is made to Dr. V. R. Boswell for assistance in the statistical treatment of the figures.

<sup>\*</sup>Expressed in percentage. <sup>b</sup> For 5 degrees of freedom 5 per cent point=11.1; for 1 per cent point 15.1.

The data submitted by the different participants are shown in table 6, in which the frequency distribution of spores is arranged in micron classes.

An examination of the data of table 6 shows that the mean length between extremes is only 1.9 microns (A, I, and E), a difference that some mycologists might not consider large enough to be determinative of different species. The differences between the mean lengths obtained by other participants are still less. It is interesting to note also that the mode of 7 out of 9 sets of measurements fall in the 40 micron class and two in the 37.5. There is considerable difference, however, between some of the sets in the maximum ranges. For minimum sizes one participant (B) reports one conidium in the 25-micron class and one (A) in the 27.5 class, while the shortest measurement made by one individual (H) was in the 32.5 micron class, and another participant (I) measured no conidia shorter than 35 microns in length, of which there were six. The range in microns covered by B on the one hand and H and I on the other, represents quite a variation, although the mean length between the two sets is less than one micron. The difference in length of the smallest conidia in these two classes, however, is 10 microns, while the average length differs by less than one micron.

A statistical treatment of these data shows significant differences between the results obtained by some of the participants, the extremes being represented by G and I. On the other hand there is no satistically significant difference between measurements made by A and B and those made by some of the other participants. Nevertheless the indications are that on the basis of the results in table 6, the

participants would not have agreed on the species represented by the culture from which the conidia were taken.

Inasmuch as statistically significant differences occur in the spore measurements of 9 investigators made from the same preparation, even greater differences are to be expected where the cultures of the organisms are exposed to different environmental conditions.

The variations that occur among the different participants may have been due to several causes, among which may be mentioned: (1) unconscious selection of large, medium, or small conidia; (2) measuring conidia in different fields of the spore preparation; and (3) error in judgment as to the nearest line on the scale of the eyepiece micrometer. Any one factor or a combination of these factors probably could cause the differences indicated in table 6.

#### SUMMARY

The effect of sunlight and artificial irradiation on the length of the 3-septate conidia was studied for three species of *Fusarium*, grown on several different culture media.

The conidia were considerably longer in cultures grown in the light than in those grown in the dark. Cultures exposed to sunlight for 3 hours daily at room temperature produced spores much longer than did cultures grown in the dark.

The exposure (light or dark) of the cultures for the first two days after inoculation had little effect. Cultures held in the dark for the first two days and then irradiated for the remainder of the growth period produced spores about equal in length to those exposed to light from the beginning. If, on the other hand, the culture was incubated in the dark for the first 4 days following inoculation, the results were about the same as when the cultures were kept in the dark during the entire incubation period. If, however, the cultures are irradiated for the first 4 days following inoculation and then shifted to a dark situation, the results were about the same as when they are grown in the light during the entire growth period.

Sporodochia and pionnotes were more copious in cultures in the light than in those grown in the dark.

Vegetative growth was most abundant in the dark. The difference in length of spores from cultures grown in light and in dark under otherwise identical conditions was much greater than the difference used as a means of separating certain species.

The maximum number of macroconidia occur in the light while microconidia predominate in the dark.

Cultures incubated in the light generally give more abundant sporodochia or pionnotes and produce larger and more numerous macroconidia than those grown in the dark.

Statistically significant differences occurred when different investigators measured conidia from the same microscopic preparation.

## ORGANIC ACID CONTENT OF CORN PLANTS AS INFLUENCED BY PH OF SUBSTRATE AND FORM OF NITROGEN SUPPLIED 1

Cecil H. Wadleigh and John W. Shive

THE PRONOUNCED influence of the presence of ammonium nitrogen in the growth substrate upon the general appearance and the mineral composition of corn plants grown in sand culture has been pointed out in previous papers (Wadleigh, Robbins, and Beckenbach, 1937; Wadleigh and Shive, 1939). This was especially manifested by the almost complete absence of chlorosis and by the significantly lower base content found in the plants supplied with a culture solution containing both ammonium and nitrate nitrogen in approximately equivalent proportions than in those supplied with nitrate as the sole source of nitrogen. It was also pointed out (Wadleigh, Robbins, and Beckenbach, 1937) that those plants supplied with nitrogen in the form of a cation had an appreciably lower pH of the expressed sap than had those supplied with nitrate as the sole source of nitrogen. In the previous paper, evidence concerning a relationship between the pH and iron solubility of a culture medium was presented together with a consideration of the probability that iron availability within the tissues may have a direct bearing upon chlorotic intensity.

The works of Harrar and Germann (1931, 1932) and of Smythe and Schmidt (1930), showing the greater solubility of organic forms of iron over inorganic forms in neutral or alkaline media, suggested the possibility that the organic acid anions present in the plant might have some bearing on the solubility of iron within the plant. The present work was undertaken to investigate the possibility that iron availability in the plants may be influenced by amounts of certain organic acids present in the plant.

The extensive studies of Pucher and Vickery and their associates have greatly simplified and improved the procedure of analyzing plant tissue for small quantities of certain organic acids. Their methods (Pucher, Vickery, and Wakeman, 1934a,

1 Received for publication February 23, 1939.

Journal Series paper of the New Jersey Agricultural Experiment Station, Department of Plant Physiology.

1934b; Pucher, Vickery, and Leavenworth, 1934) make possible the detection of oxalic, malic, and citric acids, and they provide a means of determining total titratable organic acids. Tartaric acid was determined by the method of Underhill et al. (1931). These acids are by no means the only ones existing in plants. Succinic, malic, fumaric, glutaric, glycolic, and others are to be found in various species of plants in varying amounts. The chemical similarity of many of these acids mitigates against a satisfactory assay when present in relatively small quantities. However, Pucher and his associates were able to account for 80 per cent of the acidity in the leaves of the tobacco plant by determinations for oxalic, citric, and malic acids.

In the present study, the tissues used for the organic acid analyses were parts of the same plants which were considered in the previous studies (Wadleigh, Robbins, and Beckenbach, 1937; Wadleigh and Shive, 1939). It is needless, therefore, to repeat the description of the technique used in growing them.

RESULTS AND DISCUSSION .- Plants receiving nitrate nitrogen only.-Repeated tests failed to reveal the presence of tartaric acids in sufficient quantities for detection. The results of the analyses for oxalic, malic, citric, and total acids are shown in table 1. The total organic acid content of these corn plants varied from 0.79 milli-equivalents per gram dry weight at pH 4.0 to 0.98 milli-equivalents per gram dry weight for plants grown at pH 8.0. There was a marked tendency for total organic acid to increase with increase in pH of the growth medium. However, the plants grown at pH 3.0 showed a higher total organic acid content than did the plants grown at pH 4.0 or 5.0. It is of interest to compare the values herein reported for corn with those reported by Pucher et al. (1934a) for tobacco leaves. They found an organic acid content of from 1.6 to 2.4 milli-equivalent, per gram dry weights which represents from two to three times the corresponding values for corn plants.

Table 1. Organic acid content of corn plants grown in sand supplied with nitrate as the sole source of nitrogen.

pH of sub- strate	Total organic acids, M.E. per gram	Oxalic acid, per- centage dry wt.		Malic acid, per- centage dry wt.	Malic acid, M.E. per gram	Citric acid, per- centage dry wt.	Citric acid, M.E. per gram	Acids unaccounted for M.E. per gram
3.0	0.842	0.062	0.014	1.25	0.187	0.130	.020	0.621
4.0	0.789	0.036	0.008	1.42	0.212	0.12	.019	0.550
5.0	0.808	0.054	0.012	1.56	0.233	0.18	.028	0.525
6.0	0.956	0.145	0.032	1.69	0.252	0.23	.036	0.636
7.0	0.956	0.196	0.043	1.83	0.273	0.24	.038	0.602
8.0	0.984	0.178	0.040	1.72	0.258	0.27	.043	0.643

The oxalic acid content of the plants varied considerably, ranging from 0.036 per cent in plants grown at pH 4.0 to 0.196 per cent in those grown at pH 7.0. This acid tended to increase in plants grown at the higher pH levels, but the amount found in the plants of any treatment was rather low and made up only a very small portion of the titratable organic anions of corn. Citric acid was also found to be rather low in these corn plants, varying from 0.12 in plants grown at pH 4.0 to 0.27 per cent in those grown at pH 8.0. This acid likewise was higher in amount in the plants grown at the lower H-ion concentrations than in those grown at the higher H-ion concentrations. However, it accounted for only about 2 per cent of the titratable organic anions in corn, and furthermore, this low value contrasts markedly with the value of 2.8 to 3.0 per cent found by Pucher et al. (1934) in the leaves of the tobacco plant. Malic acid was found in appreciable quantities in these corn plants, ranging from 1.25 per cent to 1.83 per cent in plants grown at pH levels of 3.0 and 7.0, respectively, with a consistent increase in amount present in the plants with progressively higher pH values of the media in which the plants were grown. About 25 per cent of the total organic acid could be accounted for by the malic acid content. Although the values recorded in table 1 might indicate that the corn plant contains a rather large quantity of malic acid, it should be pointed out that Pucher et al. (1934b) found from 4 to 9 per cent malic acid in tobacco leaves.

A significant point brought out by the data in table 1 is the large proportion of titratable organic acids which could not be accounted for by the individual analyses. That is, the specific acids determined account for only about 30 per cent of the total organic acid anions in corn, whereas Pucher and his coworkers were able to account for about 75 per cent of the total organic acids in the tobacco plant.

It appears logical that the increased accumulations of organic anions in the plant grown at progressively higher pH levels might be due to increased accumulations of absorbed cations, which, on combining with the organic anions and possibly precipitating them, would render them less susceptible to further oxidation. However, a corresponding increase in base content of the plants grown at pro-

gressively higher pH levels was not found. In fact, the base content of plants of all treatments, excepting those grown at pH 3.0 was practically identical. Furthermore, the plants grown at pH 3.0, which contained an appreciably lower quantity of total base than did the plants grown at higher pH levels, were found to contain a higher quantity of total organic acids than the plants grown at pH 4.0 or pH 5.0. In view of the rather complete absence of a correlation between these components, it should be made clear that the methods for determining organic acids detect not only the free acids but also salts and esters of these organic acids, and all of these form a composite sample. The total base content values are also subject to similar stipulations. Thus, even though very pronounced relationships might have existed between the organic acid content and the bases present in certain corresponding tissues of the plants grown at the various pH levels, such relationships might easily have been masked by the composite sampling used and the method of analyses employed.

At first glance, it might appear that the data of table 2 show little correlation between "soluble" iron and organic acids in the plants grown at different pH levels. However, it may be of some significance that the plants grown at pH 4.0 were lowest in both soluble iron and organic acids. Furthermore, the plants grown at pH 3.0, which did not follow the general tendency with respect to the relation between organic acid content and pH of the growth medium and which contained a higher percentage of these acid anions than did the plants grown at either pH 4.0 or pH 5.0, showed the highest "soluble" iron (Ingalls and Shive, 1931) content. The plants grown at pH 8.0, which showed a relatively high soluble iron content and which were free from chlorosis, contained the highest percentage of organic acids.

On the whole, there appears to be no significant correlation between pH of the expressed sap and the organic acid content of the plants. This is not surprising, since, as has been pointed out many times, there is little correlation between total and active acidity of plant juices due to the divers buffering substances present.

<sup>2</sup> The methods for determining total and "soluble" iron were those used by Ingalls and Shive (1931).

Plants receiving both nitrate and ammonium nitrogen.—In addition to the lower base content observed in the plants grown in a substrate containing both ammonium and nitrate nitrogen than in those grown with nitrate alone as the souce of nitrogen, it was interesting to note also that the organic acids were present in the plants of this series in somewhat smaller amounts than in those of corresponding cultures of the preceding series. Table 3 presents the total organic acids, oxalic acid, malic acid, and citric acid found in the plants of this series. Total organic acids varied from 0.725 to 0.905 M.E. per gram of dry plant substance, the respective amounts varying directly with the pH of the substrate. Oxalic acid varied between the limits of 0.066 per cent and 0.188 per cent, with a consistent increase in amount as the H-ion concentration of the growth medium was decreased. Malic acid varied from 0.76 per cent to 0.152 per cent and citric acid from 0.04 to 0.21 per cent, each showing the same direct correlation with pH of the substrate as did the oxalic acid content. Almost without exception, all the organic acids were found to be lower in the plants of this series than in those of the corresponding cultures grown with nitrate as the sole source of nitrogen. It is especially outstanding that the plants grown at pH 3.0 contained, relatively speaking, very low amounts of these anions. Thus the data of table 3 indicate a definite relation between organic acid content of the plants and pH of the growth substrate, high organic acid content corresponding to high pH values of the growth substrate, within the limits here investigated, and low acid content corresponding with low pH values of the substrate.

A satisfactory explanation of this relationship is at present not forthcoming. It is known that organic acids are continually being formed in plants as a result of proteolysis and oxidation of sugars, and that at least some of these organic acids are themselves continually being further decomposed by oxidation. If an organic acid should form an insoluble salt with a given cation, it should become resistant to further oxidation and should tend to accumulate in the plant. Thus, any condition favoring the precipitation of the organic anions should favor the accumulation of these anions.

It appears from the data of table 4 that there is a direct correlation between the pH of the expressed sap and the accumulation of organic acids. The significance of this relationship is emphasized by the fact that both the pH of the expressed sap and the organic acid content of the plants of the preceding series showed higher values than they did in the plants of the corresponding cultures of the series here considered. Titratable acidity of the expressed sap appears to vary inversely with the content of organic acids, as indicated by the data of table 4. This is not surprising, since, as already indicated, the variations in titratable acidity could, for the most part, be accounted for by variations in phosphorus content of the expressed sap. This comparison of the variations in titratable acidity of the ex-

Table 4. Organic acids, total bases, soluble iron, and titratable acidity of the expressed sap of plants grown in sand supplied with both nitrate and ammonium nitrogen in approximately equivalent proportions.

pressed sap with variations in organic acid content further suggests that the accumulation of organic acids may be due to precipitation, since their accumulation did not affect the buffer capacity of the expressed sap.

There was no marked relationship between the variations in organic acids and total bases. It is quite evident, however, that the plants grown at pH 3.0 showed by far the lowest values for both these components. As previously pointed out, both these constituents were lower in the plants of this series than in the plants of corresponding cultures of the

preceding series.

As previously stated in presenting the results of the preceding series, little correlation was observed between the soluble iron content and the organic acids present in the plants grown with nitrate as the sole source of nitrogen. The data of table 4, on the other hand, indicate a direct relation between the soluble iron content and the organic acids in the plants grown with both ammonium and nitrate as the sources of nitrogen, within a pH range of the substrate extending from pH 3.0 to 6.0.

The results of several investigators (Harrar and Germann, 1931, 1932; Smythe and Schmidt, 1930) would lead to the anticipation of such a relationship, and while it is quite possible that the present observation may carry some significance, it might be safer, without further investigation, to regard it as

merely fortuitous.

In this connection it should be emphasized that the soluble iron content was higher and the organic acid values lower in the plants of cultures in which nitrate was the sole source of nitrogen than they were, respectively, in the plants of corresponding cultures in which both ammonium and nitrate nitrogen were present. This observation opposes the above relation.

That a more definite correlation was not observed between soluble iron content and the organic acids present may be accounted for by the fact that the methods of analysis do not differentiate between soluble and precipitated organic anions in the plants. It is interesting to note, however, that the corn plant shows a relatively low content of organic acids and that it displays a correspondingly low degree of

efficiency in the utilization of its iron.

The large proportion of unidentified organic acids in the corn plant naturally gives rise to the questions of the nature and composition of these unidentified acids and their probable significance. Unfortunately, these questions can not be definitely answered. Yet, without going into the lengthy mathematical procedure, it might well be mentioned that from the titration curves of the extracted juice the value dpH/dB (Small, 1929) was determined by drawing a tangent to the curve at the point corresponding to the pH of the expressed juice. The phosphate content and the malic, oxalic, and citric acid content of the extracted juice were known as was also the pH of the expressed juice which had a value

of pH 5.5 to 5.7. Since the pK1 and pK2 values of phosphoric acid are 2.10 and 7.21 (Small, 1929), respectively, it is apparent that the expressed juice of the plant is buffered at a pH at which phosphates have a comparatively low buffer value. Calculations revealed that the phosphate content (which in these plants was relatively high) of the corn plants could account for only 15-20 per cent of the buffer activity at the pH of the expressed juice. Likewise, malic acid, with a pK2 value of 5.11 becomes relatively low in buffer activity at a pH value of 5.6 to 5.7. This relation has been illustrated and discussed by Small (1929). The malic acid content of these plants could account for only 10-15 per cent of the buffer activity observed at the pH value of expressed sap. Succinic acid has a pK2 value of 5.6, indicating that it could be a very active buffer in expressed corn sap at the pH of the sap. By assuming that the unaccounted for organic acids might be primarily succinic acid, and by taking into account the malic and phosphoric acid present, it was possible to calculate a value for dpH/dB at the pH of expressed sap which was strikingly close to the observed value. However, a satisfactory method for determining small quantities of succinic acid was not at hand, and, consequently, no definite statement can be made relative to the actual presence of succinic acid. It is apparent, however, that few other substances common to plants have the physical characteristics which would fit the experimental observations.

### SUMMARY

Oxalic, malic, citric, and total organic acids were determined in corn plants grown at various pH levels, the cultures of one series being supplied with nitrate nitrogen only and those of the other with both nitrate and ammonium nitrogen.

The total organic acid content of corn plants varied between 0.7 and 1.0 milli-equivalents per

gram dry weight.

Oxalic and citric acids were present in small amounts, varying from 0.05 to 0.27 per cent of dry weight.

Malic acid was present in appreciable quantities, varying from 0.8 to 1.8 per cent of dry weight.

Only 25-30 per cent of the total organic anions were accounted for.

The organic acid content of the corn plants increased with increase in pH of the substrate.

Plants grown with ammonium and nitrate nitrogen contained less organic acids and had a lower base content than plants grown with nitrate as the sole source of nitrogen.

The data secured do not show any definite interrelationship between soluble iron content and organic acids in corn plants. Corn plants under treatments here considered were relatively low in both organic acids and soluble iron.

### THE EMBRYOGENY OF SEQUOIA SEMPERVIRENS WITH A COMPARISON OF THE SEQUOIAS <sup>1</sup>

### J. T. Buchholz

THE REDWOOD, Sequoia sempervirens, has been investigated embryologically by Shaw (1896), Arnoldi (1899, 1900), Lawson (1904), and Looby and Doyle (1937). Strasburger (1872, 1879) described only the cone, ovules, and vascular supply of the cone scale. There are a number of points of disagreement in the earlier embryological descriptions. Although Looby and Doyle cleared up many disputed features concerning the gametophytes and fertilization, their account, in so far as it pertains to the embryo, is inadequate, except for the proembryo stages. While in California in 1936 the writer obtained a series of stages of the gametophytes before and including fertilization and made a careful study of the embryogeny for purposes of comparison with S. gigantea. Because I am using my own figures in this paper, it is necessary to repeat a number of facts and details concerning the gametophytes which were previously observed by others, and there are still some uncertainties which await further investigation.

A relatively small tree about 40 feet high in a group found in cultivation on the grounds of Stanford University was selected for this investigation. Although some cones on this tree were within reach, it was soon found that those situated high on the tree were not only larger, but also better pollinated. A specially constructed bamboo pole tipped with a snare was used to reach cones up to 30 feet from the ground, where they were very abundant. These

1 Received for publication December 22, 1938.

In connection with my Sequoia investigations I wish to acknowledge the courtesies of the United States Forest Service, the Carnegie Institution of Washington, Stanford University, and the University of California.

high ones were found to have about 60 per cent good ovules, while the lower group had less than 30 per cent good ovules. For this reason nearly all the material used for sectioning and dissection came from cones situated high up on this tree.

Additional material was collected from the Palo Colorado Canyon south of Carmel. This is in the cooler fog belt, and the stages observed were not as advanced. In this location, where the Redwood is found in a native stand but near the southern extremity of its region of distribution, there were very few healthy seeds in the cones that could be reached, but there were many cones high up in the trees. The cultivated trees at Stanford University in the Santa Clara valley were found to be much more productive of good seeds than any other location which was visited in this more southern region. Since Lawson collected his material at Palo Alto, it seemed desirable to obtain the material for a reinvestigation of this species from the same source, but the dates for my stages are about a month earlier than the dates given by Lawson for corresponding stages. On the other hand, the dates given for fertilization and the various stages of the embryogeny might be considerably later than those given by Lawson if the cones were obtained in the native region, either farther north or bordering the cool California coast at the same latitude. The material was killed and sectioned by the same methods as for the Big tree (Buchholz, 1939).

Figures 1 and 2 represent tranverse sections of an exceptionally large nucellus and female gametophyte. In figure 1 slightly above the middle, many archegonia or enlarged archegonial initials are

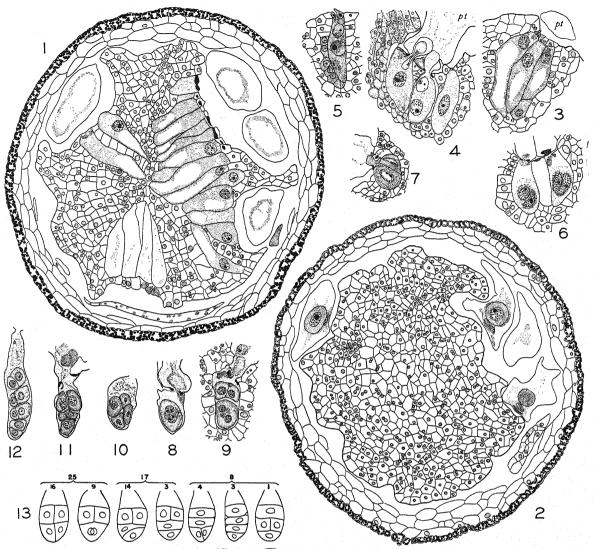

Fig. 1-13.—Fig. 1. Transverse section through upper half of nucellus of Sequoia sempervirens containing female gametophyte with many archegonia adjacent to 4 pollen tubes. A second female gametophyte may be seen below, in free nuclear stage, crushed against nucellus. May 20. ×100.—Fig. 2. Transverse section below middle of female gametophyte and below the region of archegonia (same ovule as fig. 32). Three of the pollen tubes show body cells and one or both of the tube and stalk nuclei. Part of a crushed third female gametophyte is shown at the lower right.  $\times$ 100.—Fig. 3. Archegonial group showing three archegonia near a pollen tube (pt). No ventral canal nucleus could be found. May 24. ×100.—Fig. 4. Fertilization. The archegonium at the extreme right has egg nucleus centrally placed but shows no trace of a ventral nucleus. The other two archegonia are being penetrated by sperms. In the one at the left the top of the egg is covered by dense cytoplasm which came from the sperm. The nucleus in the act of entering is shaped like an hour glass, with nucleolus likewise elongated. In the other archegonium the male nucleus has entered, leaving most of its cytoplasm outside in the pollen tube. Note that the male nucleus appears slightly smaller than the egg nucleus. May 27. ×100.—Fig. 5. Fertilization stage similar to most advanced stage in fig. 35 to show comparative size of male and egg nuclei. This archegonium shows a group of large deeply-staining jacket cells at the left. May 27. ×100.—Fig. 6. Fertilization of two archegonia with another archegonium between. The unequal sperm and egg nuclei are in close contact and both surrounded by a more deeply staining zone of cytoplasm. These two archegonia were entered by sperms from different pollen tubes. The sperm cytoplasm partly inside and partly outside may be recognized by its deeper staining quality, but this male cytoplasm does not extend to the lower part of the egg where the embryo will be formed. May 26. ×100.—Fig. 7. Two-celled proembryo showing remains of sperm cytoplasm in pollen tube. May 28. ×100.—Fig. 8. Proembryo of S. sempervirens, showing wall formation after the first division of the zygote. May 28. ×100.—Fig. 9. Proembryo forming walls after the second division, resulting in 4 cells. May 29. ×100.—Fig. 10, 11. Four-celled proembryos with different arrangement of cells.—Fig. 12. Proembryo with 4 embryo units arranged in a row, with each unit already divided into a smaller embryonic cell and a primary suspensor cell. May 29. ×100.—Fig. 13. Diagrams to show frequency of distribution of variations in cell arrangement in fifty 4-celled proembryos which were carefully examined.

shown, and these continue to be numerous toward the micropylar end in nearly all sections. Some of these archegonia may be fully developed, but most of them have not reached the mature stage. In sections at this level and upward toward the tip of the nucellus, the archegonia may be in the one-celled archegonial initial stage, or they may have formed the primary neck cell; sometimes the latter has divided. Smaller gametophytes have smaller numbers of archegonia, especially if fewer pollen tubes are present. In comparison with the Big tree, the archegonia are not only larger but many times more numerous.

Previous investigators have pointed out that there are usually several female gametophytes present in earlier stages of development and that all but one of these abort. This feature was easily confirmed by dissection. The same thing is shown in many later stages. Figure 1 shows, at the lower margin of the figure, the flattened remains of an aborted female gametophyte which is still in the free-nuclear stage of development, and in the lower right margin of figure 2 is a portion of another which had become cellular. It is interesting to note that the contents of the group of archegonia that lie opposite the first named abortive female gametophyte have disintegrated, while those that lie next to pollen tubes are more or less normally developed. Some of the archegonia shown in figure 1 are still one-celled and represent only enlarged archegonial initials, others have cut off the primary neck cell; in some the neck cell has divided so that archegonial development is nearing completion. However, the archegonia which contain the eggs that are actually fertilized are often not quite so large as many of those shown in figure 1. Furthermore, they do not usually have large vacuoles. Figure 3 shows a typical group of archegonia which are ready for fertilization, but one of these does have a relatively large vacuole. The archegonia in which, or near which, fertilization was observed (fig. 4, 5) were found to have small vacuoles, if any. Eggs that are fertilized are usually situated in archegonia far down near the lowest limits for these structures; several archegonia may be observed only a few sections above the one delineated in figure 2.

As far as could be determined, the archegonia are all related to the surface of the female gametophyte, where neck cells may usually be identified if the archegonia are sufficiently matured. If no pollen tubes are present in an ovule, the archegonia may have a scattered distribution over the surface of the upper half of the gametophyte; if pollen tubes are present, the archegonia are most abundant on the surfaces adjacent to pollen tubes. These archegonia and archegonial initials have a dense cytoplasm and stain more deeply than other gametophytic cells.

Although the origin and development of the archegonia were not studied intensively, it appears that some of them are divided later to form ordinary cells of the female gametophyte, with some of their derivative cells remaining enlarged for a time to

form jacket cells which exist in patches adjacent to the remaining archegonia. This disposition and the abortion of some of them reduces their number. Isolated cells of this kind, when found deeply imbedded, may give a misleading appearance of archegonial initials originating within the tissue. Lawson (1904) reported that the archegonia originate within the tissue. This is probably an error; at least the functional archegonia are peripheral in origin, have cut off and differentiated neck cells next to the surface of origin, and have a definite relation to pollen tubes. Sections through archegonia may appear deep seated because their necks may be at one side rather than at their ends. The archegonium containing a proembryo in figure 7, if cut in a section vertical to the surface of the drawing and in the long axis of this archegonium and embryo, might appear completely surrounded by tissue.

The archegonia are usually grouped close together with adjacent archegonia separated only by a single cell wall. This grouping is similar to the archegonial complex of the Cupressaceae but with the important difference that the entire complex is not surrounded by a common jacket, for in Sequoia we find only scattered jacket cells or small groups of such enlarged cells, if any. Proembryos were found in archegonia with no adjacent jacket cells. Since both gametes in each pollen tube may function, the fertilized eggs or zygotes are usually situated in pairs.

Looby and Doyle have pointed out that the megaspore membrane is much thinner in S. sempervirens than in S. gigantea. This difference was obvious in my studies. Measurements show that this membrane is only slightly more than a half micron thick in the Redwood but 2-layered,  $2-3\frac{1}{2}$  microns thick in the Big tree.

As in the Big tree, the nucellus of the Redwood as well as the female gametophyte which it encloses undergo considerable growth and elongation in their basal regions, even after the fertilization stage, so that the upper portion of the nucellus is soon crowded into the space between the integuments.

Sections of four pollen tubes are shown in figures 1 and 2. In the sections which show archegonia the body cells of the pollen tubes are usually not visible; at the level of the body cells there are frequently no archegonia at all, as shown in figure 2. It appears that when fertilization takes place the male cells must actually move upward toward the micropyle in order to come to the level of the lowest archegonia unless the growth of the nucellus drags the pollen tube upward. The paired proembryos were usually observed in some of the archegonia situated farthest from the micropyle.

The body cell of the pollen tube becomes very large, much larger than the corresponding structure in S. gigantea. Likewise the pollen tubes have a greater diameter. The nucleus of the body cell was observed in mitosis forming an intra-nuclear spindle, which occurs very shortly before fertilization. The male gametes become pear-shaped or more or

less nearly spherical with a pointed end, resembling a tear drop. The pointed ends are presented to the necks of the archegonia at the time of fertilization.

In an examination of many archegonia I found several abnormal instances of large or greatly elongated archegonia with two nuclei, one in which there were three and another with four. These extra nuclei were not caused by fertilization, nor was it certain that they represented the division of the central cell nucleus to form a ventral nucleus and an egg nucleus. These abnormalities may have developed either because walls failed to form in the subdivision of archegonia to form jacket cells or because there was a fusion of neighboring archegonia or archegonial initials. Such abnormal archegonial structures were relatively rare and in positions where eggs were usually not fertilized. After examining thousands of archegonia in stages just before fertilization and at the time of fertilization, Lawson's figures of ventral nuclei become less convincing. Although I observed conditions similar to his figure, my impression is that these are abnormalities and that the ventral nuclei are not regularly formed in Sequoia sempervirens. This is a problem that awaits further investigation.

Many stages in fertilization were observed. A few are illustrated in figures 4, 5, and 6. Figure 3 shows the two male gametes of a pollen tube in the act of entering the eggs of two adjacent archegonia. In the figure at the left some of the male cell cytoplasm may be observed at the top of the egg cytoplasm (staining differently), and the nucleus is squeezing through, showing a nuclear membrane shaped like a dumbbell or hour glass, the nucleolus being likewise elongated. The egg nucleus is centrally located. In the figure at the right (the middle archegonium of this group) the nucleus of the other male cell has entered the top of the egg and the egg nucleus has migrated farther down. Most of the male cell cytoplasm has remained outside, some has entered and shows near the top in another section of the series to which figure 4 belongs. Eventually only the nucleus of the male cell actually contributes to the union of cells. The sexual nuclei migrate to the base of the egg, and the foreign cytoplasm remains at the top near the entrance, so that it appears not to be included in the zygote, which occupies only the lower two-thirds of the archegonium at the time of the first division.

The male nucleus is somewhat smaller than the egg nucleus. This point was carefully checked and is shown in figure 4 (middle archegonium), in figure 5, and in the two zygotes of figure 6. This is a minor detail in which my observations differ from those of Looby and Doyle (1937). Sometimes darkstaining patches appear in the egg cytoplasm, but these are not as conspicuous as the "Hofmeister bodies" in the eggs of pines and many other conifers at the time of fertilization.

After the sexual nuclei are brought into contact, as in figure 6, a denser zone of cytoplasm appears around both of them, a phenomenon of fertilization

reported in other conifers, and the cytoplasm occupying the upper third of the archegonium begins to disorganize.

THE EMBRYO.—The anaphases and telophases of the first division of the zygotic nucleus were observed. The first division is usually transverse to the long axis of the archegonium. Figure 8 shows a very late telophase in which the wall is forming between nuclei that have divided. This is a normal cell division forming a cell plate, as will be seen also by comparing figure 9, where the first two cells have become dissociated. Thus the writer confirms the fact pointed out by previous investigators that in the proembryo of S. sempervirens there is no free-nuclear stage. The proembryo throughout the first two cell divisions occupies about two-thirds of the lower part of the archegonium. Each zygote normally forms a proembryo of 4 cells, each of which is a potential embryo initial, but soon after this 4-celled stage the entire proembryo may enlarge and crowd all adjacent structures.

Figures 7-12 show several of the types of cell arrangement found in different proembryos. Fifty proembryos were examined and classified as nearly as possible into the various categories of cell arrangements with frequencies shown by numerals in the diagrams of figure 13. Thus it may be seen that figures 9 and 10 are the more common type of arrangement and that figures 11 and 12 represent the less common types. Figure 12 shows an 8-celled proembryo in linear arrangement, but here there are really four 2-celled embryo units. Each of the four cells has divided to form an enlarging primary suspensor cell and a smaller embryonic cell. Probably the shape of the archegonium and its position with reference to the pollen tube on the one hand and the axis of the female gametophyte on the other are factors in determining the type of cell arrangement in the proembryo.

Looby and Doyle (1937) have recorded several similar variations in the 4-celled proembryo so that my study confirms their work in its essentials and adds a quantitative estimate of this variation. Otherwise the facts concerning the proembryo given by Arnoldi (1900), Shaw (1896), and Lawson (1904) were so incomplete and fragmentary that a thorough reexamination and description of these stages was fully warranted. Lawson's mitotic figure of the first division of the zygotic nucleus is not convincing. It does not show the disorganizing cytoplasm in the upper third of the archegonium and may represent an archegonial initial or large jacket cell which is dividing to form ordinary cells of the gametophyte.

Looby and Doyle, who reported that they did not observe the division of the zygote, are nevertheless correct in stating that the proembryo of S. sempervirens is four-celled. They did not pretend to give much definite information beyond this stage, and the figures which they gave of older stages were not interpreted correctly. Their text figure 5a seems to represent the formation of a four-celled proembryo,

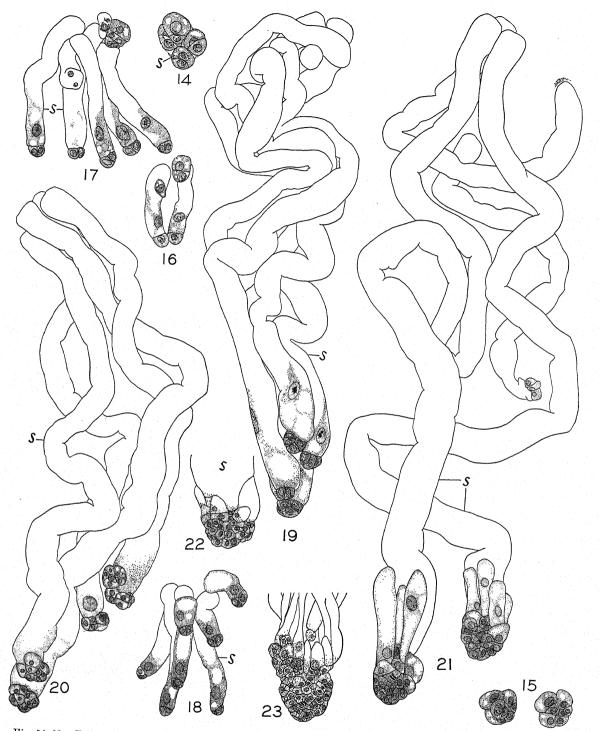

Fig. 14-23.—Fig. 14. Late proembryo from dissected specimen of Sequoia sempervirens showing each of four proembryonic cells divided into (large) primary suspensor cell (s) and (smaller) embryonic cell. May 29, 1936. ×100.— section. One embryo (at the right) has become 3-celled. May 29. ×100.—Fig. 16. Embryo system in early stage of sussuspensors elongation. One embryo initial still undivided, one divided, but with suspensor not elongated; two with fertilization of two closely adjacent archegonia, some of which are aborting to give 6 or 7 embryos. June 1, 1938. ×100.— Fig. 18. Seven embryonic units coming from two neighboring zygotes. June 7, 1936.—Fig. 19. Four embryos from the same zygote with well developed primary suspensors (s). June 8, 1936. ×100.—Fig. 20. Four embryos from the same

but 5d is more probably drawn from sections through parts of an embryo system of the stages shown in my figures 17 and 18. It is practically impossible for anyone to obtain a correct interpretation of the embryogeny in stages beyond the four-celled proembryo without the use of dissections.

Figures 14-21 represent stages in early embryonic development from dissections made in a 15 per cent sugar solution. These figures were drawn to the same scale as figures 3-12 and indicate that through enlargement the proembryo may entirely fill the space previously occupied by the archegonium, even encroaching upon the surrounding tissues. However, this increase in size is shown also in serial sections made by the usual technique. Figure 14 is a proembryo showing four 2-celled embryo initials. Each embryonic unit consists of an embryonic cell and a primary suspensor cell (s). The primary suspensor cells may be recognized because they are enlarging slightly and are becoming vacuolated. Figure 15 shows two views of a similar proembryo; the drawing at the left includes a unit found in a high plane of focus which is omitted from the figure at the right.

Figure 16 shows an early embryo system after two of the suspensors have begun to elongate. One unit remains unelongated, and another one is still single-celled. In figure 17 we have the product of two neighboring archegonia such as those of figure 4, which have given rise to six embryos on elongated suspensors and two unelongated units. One unelongated unit has become 5-celled, another one is still single-celled, and one suspensor is binucleate but bears no embryonic cell at its tip. Figure 18 shows a similar condition, seven of the eight embryos being derived from two neighboring zygotes. Embryo units may become aborted in any stage, and other variations may occur. None of the embryos on elongated suspensors have become 2-celled in figure 16; all are 2-celled in figures 17 and 18. In the proembryo of figure 15 one of the embryonic cells has divided before suspensor elongation, so that one of the units of this figure is 3-celled. This and the 5-celled unelongated unit of figure 17 indicate that there is sometimes some variation in the time of division of the embryonic cell and in the manner of division of unelongated units. However, it was found that the division in the embryonic cell nearly always separates this terminal cell into two equal parts by a vertical wall, which is parallel to the axis of elongation of the primary suspensor.

Figure 19 shows four embryos from the same zygote after the suspensors have elongated considerably. One of the terminal embryos is still 2-celled; all the others are 3- or 4-celled. Figure 20 shows a later stage. Though the suspensors have not elongated much more, the embryos have become many

celled and show lobes corresponding to the position of the individual cells of the 3- or 4-celled stages. Some of these lobes may become separated to give rise to small independent embryos, or they may disintegrate so that in either case a delayed form of unequal fractionation of embryos may be found, but the tendency is for the irregularity in the mass of cells to disappear so that in its entirety it becomes a single embryo on the end of the primary suspensor. As the terminal embryonic structures become multicellular, we find a fringe of embryonal tubes elongating around the primary suspensor as shown in figures 21 and 22, and as the suspensor collapses, these elongated embryonal tubes constitute the multicellular secondary suspensor shown in figure 23. Thus we do not have the succession of intervening embryonal tubes  $(e_1, e_2, \text{etc.})$  between the primary suspensor and the more massive secondary suspensor found in Sequoia gigantea but instead an abrupt transition from the primary suspensor to a massive secondary suspensor composed of numerous embryonal tubes nearly equal in length.

From the figures of dissected embryos it appears that a limited period of apical cell growth ensues. The primary suspensor constitutes the first segment of a hemispherical apical cell; the vertical wall of the terminal cell in figures 17 and 18 marks the second segment of an apical cell now wedge-shaped; figure 19 shows the formation of third and fourth segments in different planes. The lobing and tendency toward dissociation shown in figure 20 are no doubt along lines of division of the early segments, still shown in the older stages. The apical cell becomes difficult to follow, and the period of apical cell growth probably does not persist beyond the stages shown in my figures.

Several older stages were observed, but nothing was found which indicated that after the stage of figure 23 the embryos develop in a manner essentially different from other conifers having the same number of cotyledons. Usually only one embryo survives in the matured seed, and embryonic development is completed in the same season as pollination and fertilization. The matured embryo has two cotyledons.

Cytology.—As reported in my previous paper, S. gigantea has n=11 chromosomes. Lawson gave n=16 for S. sempervirens, while I feel fairly certain that in this species n=22. My studies in both species have thus far been made on vegetative divisions in the female gametophytic tissue, but the chromosomes should also be counted in meiosis. It is not especially difficult to count the chromosomes in a late prophase of a gametophytic cell of S. gigantea, but in the corresponding stage for S. sempervirens the chromosomes are difficult to count because of the large number of long chromosomes. I

zygote borne on primary suspensors with embryos showing strong tendency to break up into smaller embryos. June 11, 1936. ×100.—Fig. 21. Later stage with many-celled embryos that have embryonal tubes beginning to form the secondary suspensor. June 18, 1936. ×100.—Fig. 22. Tip of a similar embryo beginning to form embryonal tubes. June 20. ×100.—Fig. 23. Older embryo of many cells on a secondary suspensor composed of many well elongated embryonal tubes. June 20. ×100.

may, therefore, report, provisionally only, that the chromosome number is 22 in the gametophyte of S. sempervirens. The individual chromosomes appear to be of similar width and length in both species, so that the Redwood does not have its larger number as a result of halving of the chromosomes of the other species. The cytology, therefore, indicates a case of polyploidy, which is a phenomenon of rare occurrence among conifers. That the Redwood is a polyploid is indicated also by the relative sizes of the cells and nuclei, the relative size of the body cells for example, the relative width of the pollen tubes, the size of the cells of the proembryo, the width of the primary suspensor cells, and the size of the embryonic cells, wherever my figures of the two Sequoias may be compared.

From this we may infer that of the two species of Sequoia, the Big tree is the more primitive species, and S. sempervirens is the derived or more specialized one. It is not to be assumed that the Redwood was derived directly from the Big tree, since a dozen or more species of fossil Sequoias are known. However, it may be assumed that many of the morphological peculiarities of S. sempervirens which distinguish it from the Big tree, including the unique features distinguishing it from all other conifers, are associated with the mutation to the polyploid condition.

COMPARISON IN EMBRYOGENY OF SEQUOIAS.—The features of the embryogeny in which these Sequoias differ are surprising. The Big tree has a free-nuclear proembryo which does not differ greatly from that of the Taxodiaceae or of other conifers among the Cupressaceae. S. sempervirens has wall-formation at the first mitosis, thus differing from all other conifers. This is evidently a derived condition representing a form of specialization. S. gigantea has a structure which we may regard as a prosuspensor; in the Redwood this feature is omitted. Even if we should regard the elongating cells of the latter which I labeled s as representing instead parts of a prosuspensor, we still find a difference in that there would then be no primary suspensor. I have called these primary suspensors because they may be traced back to the division of one of the cells organized in the proembryo rather than to one of these cells with the division omitted. Only four cells are found in the proembryo of S. sempervirens, and it would be difficult to construct a prosuspensor from a 4-celled proembryo. If the 8-celled stage were used in trying to interpret a prosuspensor for this species, there would be the difficulty of not having these suspensor initial cells arranged properly in tiers, especially in such cases as that of figure 12. The first elongating cells of S. sempervirens, therefore, represent structures that are homologous with primary suspensors of S. gigantea and other conifers.

Rosette cells and rosette embryos are usually present in S. gigantea; they are not generally present in S. sempervirens. If the undivided cells shown in figures 16 and 17 were interpreted as rosette cells and the short unelongated units as rosette embryos,

there would be a difficulty arising from the fact that these may be situated in the same tier with the elongating cells. Provisionally I shall regard them as abortive initials or embryos rather than designating them as rosette elements. They all have a fair chance to form embryos, while rosette cells are usually situated above some kind of suspensor tier which prevents them from having a fair chance to contribute the embryo that may survive. Rosette cells are found in Athrotaxis, according to Saxton and Doyle (1929); so we may have here a closer resemblance between two separate genera (generally accepted as such) than between the two Sequoias.

The interpretation given to the homology of the primary suspensors permits one to recognize a similarity between these elongated cells with respect to the position of the first wall appearing in the terminal embryonic cell. Although this wall appears sooner after elongation in the Redwood than in the Big tree, it nearly always divides the terminal cell into two symmetrical halves. There is an additional similarity in respect to the fractionation of the embryos which takes place some time after the primary suspensors have elongated. This "budding" does not appear to be so clearly marked in the Redwood as in the Big tree. However, there is a difference again in that the embryonal tubes  $e_1$ ,  $e_2$ , etc., elongate at first singly, or at least more or less successively in the Big tree, while in S. sempervirens they seem to elongate more nearly in unison to form a fringe around the end of the primary suspensor. In general the elongating suspensor cells of all kinds become much longer in the Big tree, both relatively and actually.

Though not much could be found concerning variations in the manner of origin of the cotyledons, it is definitely certain that the late embryos differ; S. gigantea is polycotyledonous, and S. sempervirens is dicotyledonous.

As indicated in my previous paper, if we compare the embryo of the Big tree with that of Sciadopitys (Buchholz, 1931) we find considerable resemblance. Sciadopitys (Lawson, 1910) appears to have at least 8 (or possibly 16) free nuclei formed in the proembryo before the mitotic division in which cell walls appear, a difference which might be expected in an egg which is so very much larger. Then each of these genera has a prosuspensor, although this member is relatively smaller in S. gigantea. In both, prosuspensor elongation is followed by the formation of primary suspensors for the respective groups of embryonic units which are borne on the end of the prosuspensor. Both S. gigantea and Sciadopitys may or may not have rosette cells. When the smaller embryonic units on the end of the prosuspensor elongate, the terminal cell divides very promptly and in the same manner in both genera.

We may place Sciadopitys at one end of the series, S. gigantea next to it, possibly Athrotaxis next to this, and S. sempervirens at the end of the series. The smaller and more ephemeral prosuspensor of S. gigantea may be regarded as a prophecy of the

final elimination of this member as we approach greater specialization.

In several earlier papers I took the position that extensive cleavage polyembryony is a very primitive condition among conifers, and that all or nearly all conifers show a compound embryo indicating that they have passed through cleavage polyembryony in their evolution, so that a reduced form of cleavage polyembryony, or eventually the condition of simple polyembryony, are derived conditions. This view, which was developed as a working hypothesis about twenty years ago, has found more and more support in subsequent investigations, and has come to merit serious consideration. These Sequoias lend additional support to this hypothesis, for many other criteria indicate that the Big tree with its extensive cleavage polyembryony (nearly a dozen embryos per zygote) is the more primitive species, and the Redwood with a reduced form of cleavage polyembryony (four embryos per zygote) is the more specialized. The next step in evolution would be only one embryo per zygote, thus ending the series in simple polyembryony.

This condition of polyembryony as well as the series shown in the proembryo which ranges from 16 nuclei at wall formation (Sciadopitys) to 8 nuclei (S. gigantea) and finally wall formation at the first division of the zygote; the n=11 and n=22 chromosome numbers; the well developed prosuspensor (Sciadopitys), a more ephemeral prosuspensor (S. gigantea), and finally the absence of a prosuspensor; all these series indicate direction of evolution of these embryonic structures.

GENERAL COMPARISON OF THE SEQUOIAS.—The account given by Looby and Doyle (1937) may seem to have stressed the points of resemblance between the two species of Sequoia, and the results of their investigations may appear to minimize the importance of the differences, but their observations were mostly limited to the gametophytes. Taxonomists, at least our American botanists, have generally accepted the Sequoias as belonging to the same genus, on the basis of external anatomy. However, thus far too little has been known concerning the details of their internal morphology that have been considered important criteria in the study of relationships among other genera. Among European investigators opinions have been divided, some following our practice of including both Sequoias in the same genus, others insisting that they represent two genera and calling the Big tree Wellingtonia.

It may be timely, therefore, to list the resemblances and the differences. Among the resemblances we find a similarity in the wood structure, a similarity, except for size, in the cones, in the habit of becoming large, long-lived trees, in the general structure of the seed, in the structure of the ovule, in relative position of the gametophytes, and in fertilization. Both have cleavage polyembryony followed by a form of unequal "budding" sometimes resulting in a further fractionation of the embryo; both show much variability in the arrangement of

cells in their respective types of proembryos. Nearly all these internal resemblances as far as they are known are shared by *Athrotaxis* (Saxton and Doyle, 1929) which is everywhere recognized as a distinct genus.

Differences between the Sequoias, including the well known taxonomic differences which may be verified by comparing the full descriptions of both species in Sargent (1902), Jepson (1910), and other monographs, may be listed as follows: S. gigantea becomes the largest tree known, has a characteristic form with relatively stout branches that turn upward at their ends, while S. sempervirens is more slender, becoming the tallest tree known, and has more slender branches that are characteristically horizontal. In fact, the two species differ in eight or more gross taxonomic differences that concern the aspect and habit, the wood, the bark, the stem. etc.

In the Big tree the buds are naked, in the Redwood scaly. Furthermore, there are six or more taxonomic differences between the leaves of the two species. For instance the former has only awlshaped leaves, while the latter has dimorphic foliage, some of its leaves being small and awl-shaped, others much larger, petioled, scythe shaped, and complanately 2-ranked.

The Big tree has no vegetative reproduction, while the Redwood has abundant vegetative reproduction. The former is pollinated in April-May, while the latter is pollinated in January-February, and there are at least seven well marked taxonomic differences between the pollen cones and the ovulate cones of the two species at the time of pollination. Also, S. gigantea has seed cones 2-3 inches long and evergreen, remaining on the trees for many years after the morphological maturity of the seeds, while in S. sempervirens the cones do not exceed 11/4 inches in length and they become dry and shed their seeds within a year. Five or more taxonomic differences are found in the scales of the seed cones, and these differences include a feature not previously pointed out-namely, that the ovules and seeds are borne in two rows on the cone scale of the Big tree and in only a single row in the Redwood. Likewise the embryos of the seeds of the Big tree develop over a 2-year period; those of the Redwood require only a single season for their development. There are also two or three taxonomic differences in the

While most of the contrasts referred to above are only specific differences, they are nearly all distinct enough to be used in a key separating the two Sequoias. However, the difference in the buds, the difference in the history of development and in the persistence of the seed cones, and also the difference in the time required for the maturity of the seeds should be regarded as generic distinctions.

The difference in the size and shape of the pollen tubes is one of the gametophytic differences between the two Sequoias. There is also a difference in the size of the pollen grains, the Redwood having the larger spores. The manner of development of the female gametophytes (as well as their size and shape) is very different in the two species, the Big tree following the usual type of development in conifers, while that of the Redwood is unique. There is also the remarkable feature of a competition between the female gametophytes during development, there are many more archegonia, and the conspicuous irregularly scattered jacket cells, all characteristic of the Redwood. In S. gigantea the megaspore membrane is  $2-3\frac{1}{2}$  microns thick, while in S. sempervirens it is less than 1 micron thick. The number of chromosomes in the female gametophyte differs: n=11 in the former; n=22 in the latter. Among these gametophytic differences more than half are generic distinctions.

In summarizing the embryogeny, nine outstanding differences may be found between S. gigantea and S. sempervirens. The free-nuclear stage in the proembryo of the former, its absence in the latter; the organization of the proembryo into tiers vs. proembryo not organized in tiers; the presence of a prosuspensor in the former and its absence in the latter; are all distinctions of a grade that separate genera and families among other conifers. The difference found in the presence or absence of rosette cells, the difference in the number of embryos derived from each zygote, the difference in the successive versus the simultaneous elongation of embryonal tubes in the formation of secondary suspensors, and the difference in the number of cotyledons, are also distinctions that are of generic rank. In the Big tree the cell volume average of comparable embryonic cells is much smaller than in the Redwood, and the suspensor segments of the former are much more slender, though longer in the former than in the latter, representing differences that are probably only specific in rank.

At least 55 important differences between the Sequoias are known. More than 30 of them are concerned with the external features included in the taxonomic descriptions which have stood for many years. There are also a number of taxonomic distinctions pointed out more recently which should be added to this group, giving a total of three dozen well marked external contrasts between the two Sequoias. A great majority of the gametophytic and embryological differences are characters which are found to be of generic value among other conifers. Almost a third of the total are generic differences. The results of morphological investigations all point to one conclusion, that the two Sequoias belong to different genera.

### SUMMARY

The gametophytes of Sequoia sempervirens were investigated in stages earlier than fertilization. The pollen tubes are relatively wider and not so long as in S. gigantea and contain larger nuclei. They were found in the same position on the sides of the female gametophytes. Several female gametophytes are in

competition within the same ovule, but usually only one of them survives to maturity. Mitotic figures reveal 22 chromosomes in the tissue of the female gametophyte. The megaspore membrane is very thin. The laterally placed archegonia are numerous and occur in groups which are usually adjacent to pollen tubes. These groups superficially resemble the archegonial complex of Cupressaceae, but are surrounded only by irregularly scattered jacket cells rather than a continuous jacket. There is great doubt as to whether the ventral canal nucleus is formed. The division of the body cell, the formation of two male gametes, and their entrance into the eggs were observed. Fertilized eggs are usually found associated in pairs.

When the zygote divides, a wall, which is perpendicular, or nearly so, to the long axis of the archegonium, is formed at the first mitosis. The two resulting cells divide in various planes, so that a number of variations are found in the arrangement of cells in the proembryo. Fifty 4-celled proembryos were observed and the variations in cell arrangements tabulated. Each cell of the 4-celled proembryo may be considered an embryo initial and divides to form a primary suspensor cell and an embryonic cell. As the primary suspensors elongate independently, the four embryo units are separated, while each terminal embryonic cell is divided by walls parallel to the axis of the elongating suspensor. A brief period of apical cell growth may be recognized. No prosuspensor is formed, nor is there a rosette group as found in the other species of Sequoia. Entire embryo initials, suspensor cells, or individual embryonic cells may become aborted in any stage, thus reducing the number of embryos that appear to be derived from one or a pair of zygotes. The primary suspensor is followed abruptly by a massive secondary suspensor composed of numerous embryonal tubes, whereas in the other Sequoia there is a succession of individual embryonal tubes and a gradual transition to a massive secondary suspensor. A further budding or secondary cleavage of the embryo is also possible, but in general the entire embryonic mass borne on a primary suspensor usually contributes a single embryo in which the lobes and irregularities tend to disappear. The single embryo which finally survives embryonic competition forms two cotyledons.

The known features of the gametophytes and embryogeny are compared with those of S. gigantea, Sciadopitys, Athrotaxis, and other conifers. Many differences which are of generic value in other conifers are found between the two Sequoias. There are also many external taxonomic distinctions between them, and nearly a third of all the known differences are of generic value. From these facts it is concluded that the two Sequoias belong to different genera.

### THE USE OF INDICATOR PLANTS IN LOCATING SELENIFEROUS AREAS IN WESTERN UNITED STATES. I. GENERAL <sup>1</sup>

O. A. Beath, C. S. Gilbert, and H. F. Eppson

ONE of the most important points brought out in connection with the selenium problem of the West has been the discovery (1, 4, 5) that certain native selenium bearing plants may be used as indicators in locating seleniferous soils. These native plants may be relied upon to contain significant amounts of selenium during all or a major part of their annual growth, and hence their presence indicates the occurrence of selenium in the soils upon which they grow. We have consequently attached the name "indicator plants" to such species. An observation of equal importance, in the opinion of the authors, is the influence of many of the highly seleniferous plants in making selenium available to associated vegetation. The significance of this relationship has not been fully appreciated. It is especially important when it results in the absorption of toxic quantities of selenium by grasses, cereal grains, and other farm crops. A later report will discuss recent researches along this line of a practical nature by the authors.

The present paper deals with the different species of indicator plants so far known, their capacity to accumulate selenium, their taxonomic relationships, and their distribution—particularly with reference to the geological formations on which they occur.

It is now known that one or more native seleniferous indicator plants occur in parts of sixteen western states—including Arizona, Colorado, California, Idaho, Kansas, Montana, Nebraska, North Dakota, New Mexico, Nevada, Oregon, Oklahoma, South Dakota, Texas, Utah, and Wyoming. We do

<sup>1</sup> Received for publication February 6, 1939.

not propose to review the situation in all these states, nor are we concerned at this time with the question of how completely the data cover the conditions in any one state.

In 1934 (1) we reported that certain native plants of Wyoming could be relied upon to contain selenium if rooted in seleniferous soils derived from rocks of Cretaceous or Tertiary age.

Since then additional geological formations have been found to be capable of supporting seleniferous indicator plants. Data on these are available in published reports (3, 5). In every case, however, the seleniferous areas discovered by the authors were located by means of the selenium indicator plants. One of the most unique correlations of this type was described in a previous issue of this Journal (5) under the heading, "Selenium in Soils and Vegetation Associated with Rocks of Permian and Triassic Age."

Geological relationships.—Since 1934 geobotanical correlation studies have been extended into several of the Rocky Mountain states. One would expect that a seleniferous geological formation in one area or state could be depended upon to also show a seleniferous composition in other areas. It is not surprising, therefore, to find that geological formations such as the Steele, Niobrara, Benton shale, etc., or their equivalents are capable of supporting certain forms of seleniferous vegetation (3, 8, 12) in other states than Wyoming. Reference to geological maps of the United States enables one to locate these areas, at least approximately. The source rocks from which the Tertiary and Cretaceous sedi-

These sediments are part of the Payette formation which is Miocene in age. Near Glenns Ferry, southwestern Idaho.

ments were derived have been discussed (2, 3, 11) in earlier reports.

In most cases seleniferous rocks carry one or more of the naturally occurring selenium bearing plants. Byers (8), in his original survey (1935), failed to record any significant seleniferous vegetation in New Mexico, Utah, and Arizona. Since that time, however, seleniferous indicator plants have been found in abundance in the areas investigated in these states.

In several type areas in Wyoming it has been observed that above 8500 feet an ecological factor intervenes, so that the principal seleniferous plants disappear, while the seleniferous soil horizons may continue to considerably higher altitudes.

The significance of the selenium indicator plants is particularly important in locating seleniferous areas not heretofore recognized in the West. This paper deals in part with situations of this character. We have selected for detailed study certain areas where one or more of the selenium indicator plants occur. The areas include the White Tank Monzonite (fig. 1) intruded into the pre-Cambrian rocks of the Twenty-nine Palms area in southern California; the limestones of Pennsylvanian age in southeastern Nevada (fig. 2) and central Idaho (fig. 3); the caliche-like deposits in southern Arizona and California; the carbonaceous and limy shales of late Mississippian or early Pennsylvanian age (fig. 4) in Provo Canyon, Wasatch Mountains, Utah; the Tertiary sediments of Pliocene age (fig. 5) in the Tonto Basin; the sediments of Tertiary or Quaternary age in the Upper Verde Valley (fig. 6) of north central Arizona; and the Payette Lake sediments of Miocene age in southwestern Idaho (fig. 7). The seleniferous formations just cited are believed to be new assignments. In none of the above cases were our results negative for the vegetation of any one formation as a whole. The statement made by the authors in earlier publications that some of the indicator Astragali were capable of growing without absorbing selenium is to be interpreted as relative rather than absolute. Plants showing very low amounts are insignificant as livestock hazards. The significance of small amounts of selenium as a physiological factor for the plants was not considered at that time. In most cases, however, where low selenium values are found in native indicator plants, it may be expected that the associated soils will be lean in selenium.

Knight (3, 11) has referred to the source from which much of the Cretaceous seleniferous sediments of Wyoming were derived. The discovery of pre-Cretaceous seleniferous rocks in the area from which the Cretaceous sediments were derived is of interest.

Collections of various Stanleyas have been made in Nevada. The age and character of the rocks supporting much of this vegetation is not known to us. Seleniferous vegetation has also been collected from southeastern Idaho and from Boxelder County, northwestern Utah. Here again the formations are unknown.

The geological formations involved in the study of seleniferous soils and vegetation in western United States include rock types associated principally with three eras (fig. 8)—the Paleozoic, Mesozoic, and Cenozoic.

In order to acquaint readers who are not familiar with the geological nomenclature used in this paper, the following definitions of geological terms and their usage are quoted from a previous bulletin (11) on this subject:

The geological column comprises all the rocks of the earth's crust. It is divided into time terms and rock terms. The divisions of the geological time scale and corresponding rock terms are:

ime tern	1		Rock tern
Era		100	
Period		 	System
Epoch		 	Series
Age		 	Group
Stage		 	Formation

Era. The largest division of geological time.

Periods and systems. Geological eras are composed of a number of periods (time). Each period is represented by a system (rocks)....

Formation. The formation is the fundamental unit in the local classification of rocks. A formation may be a few feet thick or it may be five thousand feet thick. A formation may vary greatly in thickness and character from place to place, and a single formation may be composed of an alternating succession of various rock types, such as sandstones, shales, etc. Formations are names from geographical localities. For example, the Sundance formation is named from the town of Sundance, Crook County, Wyoming. . . .

Member, lentil, tongue, and lens. These are subdivisions of a formation. Specially developed parts of a varied formation are called members if they are of considerable geological extent; lentils if they are of slight geographic extent; tongues if it is known that in one direction they wedge out, laterally, between sediments of different character; lenses if they wedge out laterally in all directions.

Bed, stratum, and layer. These are the smallest units recognized in classification.

Broadly interpreted, the geological column of central Wyoming is representative of the formations or their equivalents in the Rocky Mountain region. In the discussion of geobotanical data in this paper, the authors refer from time to time to the Wyoming generalized geological column (fig. 8) in order to establish the continuity of the seleniferous character of rocks of equivalent age.

In the Paleozoic era the oldest seleniferous rocks so far discovered occur in late Mississippian or early Pennsylvanian. A representative formation is well exposed in Provo Canyon, Wasatch Mountains, Utah.

From late Paleozoic through the Mesozoic and Cenozoic the occurrence of selenium is variable. Many formations in the Permian, Triassic, and Jurassic systems do not contain enough selenium to produce toxic vegetation. Beginning with the Morrison formation (late Jurassic) and continuing on through the Cretaceous system, selenium occurrence

Fig. 8. The geological column of central Wyoming. This column is used as a standard for comparative purposes in this paper.

is common and practically continuous. Selenium in Tertiary sediments is more or less localized. This feature was discussed in earlier publications (3, 5, 11). Seleniferous rocks have been found in formations of Paleocene, Eocene, Oligocene, Miocene, and Pliocene age.

In the Hanna Basin, of Carbon County, Wyoming, the late Cretaceous and Eocene rocks are very thick. Here the Medicine Bow formation is overlain by several thousand feet of conglomerates, light and dark colored shales, brown sandstones, and coal beds. This complex aggregate of varied rock types has been divided into the Ferris and Hanna formations. Much, if not all, of the rock debris which make up these formations was derived locally from the adjacent mountains. The Ferris formation, from its basal contact with the Medicine Bow to the top, represents an exposure of considerable magnitude. The beds stand at high angles.

Xylorrhiza parryi (woody aster) in full bloom was collected on the same day from raw shale outcrops of the Ferris formation along a diagonal traverse of four miles. Woody aster is dependable as an indicator of seleniferous soil; and the selenium content of this plant provides a fairly accurate index of the corresponding selenium content of the soil. The areas from which the aster was taken are designated as A, B, C, D, and E (fig. 9). It will be observed

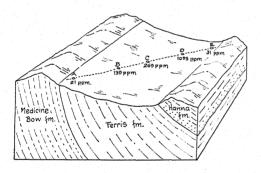

Fig. 9. Diagram showing the variation in parts per million in the selenium content in specimens of *Xylor-rhizu* collected on a diagonal traverse of the Ferris formation, Carbon County, Wyoming.

that at the point marked D the plants reached their maximum selenium content; at point A, their lowest. Soil selenium in the highly seleniferous area was found to be 4.0 parts per million, while at location A it was only 0.5 part per million. These data illustrate selenium localization in Tertiary rocks. However, in certain areas these rocks may be uniformly seleniferous when derived from source material of uniform selenium content.

SELENIUM INDICATOR PLANTS.—The primary selenium indicator plants as defined by the authors are those universally seleniferous in their annual cycle of growth. The primary group of indicator plants is centered chiefly around four genera. These include species of Stanleya, Oonopsis, Xylorrhiza, and Astragalus. The authors included Mentzelia deca-

petala in the original list of indicators. Because most species in the genus Mentzelia do not absorb selenium in toxic quantities and those that do are irregular in distribution, this genus is now placed in the secondary or intermediate class. In most instances the maximum concentration of selenium occurs in the plant's early growth. In soils with low selenium values the selenium content of the indicator plants will usually be correspondingly low.

Although some samples of the primary indicator plants have given negative tests for selenium, analysis of these species from the same soil areas at a time when the initial growth was starting has invariably resulted in obtaining positive tests for selenium. In one instance the past seeding stage of one of the major indicator plants, Astragalus bisulcatus, showed only 3.5 parts per million selenium, but a composite sample from the same area the following spring showed 135 parts per million selenium. The surface foot of soil (composite) contained 0.49 parts per million selenium.

Moxon (12) found a few Astragalus racemosus plants to be non-seleniferous when partly or fully matured. To determine definitely whether this or any other species of certain seleniferous groups of the Astragali can grow and develop normally without absorbing some selenium, it would be necessary to analyze plants at several stages of growth from the same soil area. Occasionally large thrifty Astragali may be observed approaching maturity without producing fruiting heads, or plants may have their fruits drop prematurely owing to injury by insects. More selenium accummulates in the seeds and pods of the Astragali than in the vegetative parts, consequently occasional samples may be obtained that are not representative of normal conditions.

Trelease (13) has shown that for certain species of Astragalus selenium may be an essential microtrophic element.

Species of Stanleya. - In a discussion of the species of Stanleyas that are absorbers of selenium, it is not possible to report on all of them at this time owing to the fact that the authors have not had an opportunity to obtain sufficient material for chemical analyses. Those species that are known to be dependable in their selenium absorption are: Stanleya pinnata (Pursh) Britt., S. bipinnata Greene, S. integrifolia James, S. glauca Rydb., S. viridiflora Nutt., S. tomentosa Parry. It is generally true that the amount of selenium in these plants is a fairly reliable index of the quantity of selenium in the soils in which they grow. Exceptions occur, as would be anticipated. A Stanleya sample (not identified) collected near Battle Mountain, Nevada, gave a negative test for selenium. The surface soil (1st foot) had 2.20 parts per million selenium. The plants, as received, were past the seeding stage and considerably weathered. Young thrifty plants from the same area would probably be definitely seleniferous in a soil carrying this amount of selenium providing that the seleniferous condition continued to the depth of the feeding roots.

Fig. 10-14.—Fig. 10. The club-like heads of Stanleya tomentosa Parry, Owl Creek Valley, Hot Springs County, Wyoming. The formation here is of Triassic age.—Fig. 11. Aster adscendens Lindl. in common with other species of the genus usually occurs in dense patches. It is seleniferous when rooted in selenium bearing soils.—Fig. 12. Xylorrhiza parryi (A. Gray) Greene. Each clump is a potential source of available selenium. Southern Albany County, Wyoming.—Fig. 13. Stations indicate areas from which comparable plant samples were taken for selenium analysis. Central Albany County, Wyoming—Fig. 14. In the immediate foreground are several clumps of seleniferous Astragalus praelongus Sheld. (Pre-bloom.) These plants are growing in rocks of Triassic age (basal). Near south entrance of Zion National Park, Utah.

The Stanleya species vary in their selenium absorbing properties. Stanleya pinnata and S. bipinnata normally will be more seleniferous than S. viridiflora under similar stages of growth and environmental conditions. Specimens of S. viridiflora of unusual growth and thriftiness have in several instances given very low selenium values. This is particularly true of samples from certain areas in Idaho and Nevada. Their value as indicators of a seleniferous soil, however, is significant in that their occurrence frequently suggests the presence of other, highly seleniferous plants in the immediate vicinity.

Stanleya integrifolia usually carries a toxic amount of selenium but does not run as high as S. pinnata or S. bipinnata under similar conditions of growth and habitat. Stanleya tomentosa Parry has not been reported to occur (fig. 10) outside the Big Horn Basin, north and central Wyoming. There are a number of Stanleya species in the western United States about which no selenium data are available. Representative valid species are S. runcinata Rydb., S. albescens Jones, S. canescens Rydb., S. elata Jones, and possibly others.

Species of Oonopsis.—The species in this genus that have been examined for selenium show a decided affinity for it. The present list includes: Oonopsis condensata A. Nels., O. argillacea A. Nels., O. foliosa (Gray) Greene, (Aplopoppus fremontii Gray), O. engelmannii (Gray) Greene.

Of the several type species analyzed for selenium, Oonopsis argillacea has shown the lowest average

content under comparable conditions.

The species not analyzed are: Oonopsis multicaulis (Nutt.) Greene, O. wardii (Gray) Greene, O. monocephala A. Nels.

The tendency for some species to yield high results and others average to low is quite generally applicable to all the seleniferous indicator plants.

Species of Xylorrhiza.—The most significant species of the Xylorrhizas in so far as selenium absorption is concerned is X. parryi (Gray) Greene. It also has a wider distribution than any other species in the Rocky Mountain area. Other seleniferous species include: X. villosa Nutt., X. venusta (M. E. Jones) Heller, X. glabriuscula Nutt.

Analysis of X. villosa collected from a number of soil types shows this species to be a moderate to low absorber of selenium compared with X. parryi and X. glabriuscula under comparable stages and condi-

tions of growth.

Species that have not been analyzed are: X. coloradensis (Gray) Greene, X. brandegei Rydb., X.

lanceolata Rydb.

The seleniferous *Xylorrhizas* as a group yield the highest amount of selenium in the early stages of growth. After the seeds are well developed, the tops of the plants wither and are scattered by weathering.

Aster abatus Greene, originally named Xylorrhiza tortifolius Gray, has been collected from several areas in California and Utah, but no selenium has been found in any of the samples. (See results on Asters.) By the criterion of selenium absorption, this species is not a Xylorrhiza. From the assembled data, it appears fairly certain that all the dominant species of the genus require selenium for their existence. Since Xylorrhiza tortifolius (Aster abatus) is negative in this respect, we conclude that X. tortifolius is not a Xylorrhiza but an Aster. Type specimens from Utah and California contained no selenium.

Species of Astragalus.—This is a particularly interesting genus and constitutes the most important group of the selenium indicator plants. It is the only genus in which one can attempt to separate by genetic differentiation selenium-absorbing species from non-absorbing species.

For example, no Astragalus having an inflated pod has as yet been found capable of absorbing selenium in toxic quantities from naturally occurring seleniferous soils, whereas all the available evidence points to universal absorption by species characterized by a "bisulcate" pod. Marcus E. Jones (10) classified the species of Astragalus of the United States into twenty-nine groups. His division was

based upon genetic characteristics. As a starting point in our investigations of the seleniferous Astragali of the western states, we chose Jones' classification for correlation studies. Of the twenty-nine groups listed by Jones, we have had an opportunity to examine one or more species in most of them. The dominant selenium absorbing Astragali now known include species in but five of the twenty-nine groups. These are:

Astragalus haydenianus Grav . Astragalus oocalycis Jones Astragalus scobinatulus (Sheld.) Bisulcati Astragalus bisulcatus (Hook.) Gray Astragalus urceolatus Greene Galegiformes Astragalus racemosus Pursh (Astragalus flavus Nutt. OcreatiAstragalus flaviflorus (OK.) Sheld. Astragalus confertiflorus Gray Astragalus toanus Jones Podo-sclerocarpi Astragalus grayi Parry Astragalus pectinatus Dougl. Astragalus preussii Gray Astragalus preussii var. latus Jones Astragalus pattersonii Gray Preussii Astragalus praelongus Sheld. Astragalus sabulosus Jones Astragalus eastwoodae Jones Astragalus limatus Sheld.

It is evident from our preliminary studies that there is a definite tendency toward a genetic segregation of the selenium absorbing properties so characteristic in some Astragali and entirely lacking in others. The Homalobi group, for instance, includes some twenty-three type species widely distributed in western United States, and yet none of the species so far examined have carried significant amounts of selenium. The large group of Inflati, the Reventi-arrecti, Uliginosi, Hypoglottides, etc., also are non-absorbers. The authors have not been able to obtain representative species in the Sparsiflori, Alpini, Strigulosi, Atrati, or Micranthi groups.

In presenting data to support the hypothesis that some Astragali are seleniferous and others not, depending upon genetic relationships, the authors wish to go only as far as the facts would warrant. Until all the important species in the twenty-nine groups as outlined by Jones have been carefully checked, one cannot hope to arrive at final conclusions.

Among systematic botanists, both past and present, we find divergent opinions on Jones' revision of the Astragali. This is a natural consequence particularly in dealing with a genus of such magnitude and complexity. In approaching the study of seleniferous Astragali from our point of view, we have found the revision of the Astragali by Jones to be the most helpful of any of the botanical references consulted. In behalf of Jones' monograph on Astragalus it must be admitted that it was prepared by a botanist thoroughly familiar with field conditions.

In so far as our investigations have gone, it is quite significant that the exceptions to our hypothesis are infrequent. One of the most prominent of these exceptions has to do with Astragalus drummondii. This species is placed in the Galegiformes group along with A. racemosus. Astragalus drummondii normally does not absorb selenium in toxic quantities. On the other hand, A. racemosus is a very dependable absorber of selenium and hence an indicator of seleniferous soil. No explanation of this variation seems to be possible at this time.

The fact that we have been able to predict that certain Astragali should be seleniferous and then confirm the prediction by actual chemical analysis warrants the suggestion that our hypothesis has some economic value. For example, Astragalus toanus Jones belongs to the Podo-sclerocarpi group. In this same division are A. grayi and A. pectinatus, which we had early found to be seleniferous. Samples of A. toanus were therefore obtained from Utah, Nevada, and Idaho. They were found to be seleniferous. In addition, A. toanus is confined exclusively to soils of a seleniferous character. It becomes a primary selenium indicator plant in the sense that it contains selenium and may be expected to occur only on a seleniferous soil.

Associated with the seleniferous Astragalus pattersonii, A. praelongus, and A. sabulosus in the group classified as Preussii is Astragalus preussii. A type sample taken from an area near Las Vegas, Nevada, was found to be definitely seleniferous on a massive limestone that carried only 0.54 parts per million selenium. The genetic association placed A. preussii in the suspected class of selenium absorbing Astragali. For this reason it was sought out from other Astragali in this area. Also, two collections of a variety of A. preussii from Utah and one from New Mexico were seleniferous.

In considering data supporting the correlation of certain seleniferous Astragali species with genetic relationships, it should be borne in mind that our interpretation of a selenium absorbing plant is based upon the dependable capacity of these plants for acquiring selenium from naturally occurring seleniferous soils. To illustrate this point from field evidence, A. carolinianus may be considered. Astragalus carolinianus L. has been collected from several typical seleniferous soils in Wyoming. Analyses of these samples show that it is definitely not a selenium indicator plant in this state. Byers (8) (Third report) has reported this species to be quite generally seleniferous. The fact that it is not a dependable absorber in Wyoming at any stage of growth places the species outside the primary indicator plants. In view of the fact that Byers gave no data from Wyoming on A. carolinianus, we are unable to check the identification of his material. Type species in the group Uliginosi, to which A. carolinianus belongs, are not selenium bearing even on decidedly seleniferous soils.

Much remains to be done in the correlation study of the selenium bearing Astragali into genetic segregations. The authors have been retarded in this investigation through their inability to secure type

samples from areas far removed from Wyoming. Preliminary investigations point toward a definite trend, but whether or not such a generalization is tenable for the Astragali as a whole, with so many key species still not analyzed, remains to be ascertained. The possibility of the genetic relationships entering into the selenium study was not initially considered. It was only after several hundred analyses had been made that our attention was directed to the fact that many of our data offered a kind of correlation not applicable to other seleniferous plant genera.

Brandegee (7) (1876) called attention to the resemblance in odoriferous principle between the flowers of Astragalus haydenianus and those of A. bisulcatus. Jones (9) (1895) mentioned Astragalus pattersonii as being a nauseous poisonous weed. Beath (6) (1917) noted that the water extracts of A. bisulcatus were markedly odoriferous. It is now recognized that many of the seleniferous Astragali emit an odoriferous principle, varying in intensity of course but nevertheless persistent. It is believed that every sample of Astragalus having the characteristic odor has been seleniferous. To the experienced plant collector this odoriferous principle is not only a fairly accurate qualitative indication of selenium, but in addition it can be depended upon for a prediction as to whether an Astragalus specimen is moderately or highly selenized. In 1937, while the senior author was seeking seleniferous vegetation in northeastern Arizona on the basal Triassic geological formation, he found in the vicinity of Winslow an Astragalus that emitted the typical odor so commonly noted in all the Bisulcati group. Later, this plant was identified as Astragalus praelongus. A. sabulosus from the Upper Verde valley in Arizona was also noticeably odoriferous. Both of these Astragali proved to be highly seleniferous.

INTERMEDIATE SELENIUM-BEARING PLANTS.—Researches have brought to the foreground the economic significance of plants of several genera which, though not restricted to selenium-bearing soils, are capable of absorbing selenium in toxic quantities when growing on seleniferous soils. Many species in this group are grazed by livestock. We propose to classify plants of this kind as intermediate or secondary indicators. A few representatives in this class are species of Aster, Atriplex, Grindelia, Machaeranthera, Sideranthus, Mentzelia, Pentstemon, Gutierrezia, etc. (8, 12). This is a very difficult group to evaluate. Preliminary field evidence shows that some native plants can absorb selenium from its naturally occurring nearly insoluble form in rocks and soils and that a host of other native plants cannot do this. In many very toxic areas the soils have become enriched with selenium through decomposition and weathering of the highly seleniferous plants-both past and present. In instances of this sort it is certain that any vegetation growing under this influence will be seleniferous. The evidence is most convincing on this point. Soils have

been taken from representative toxic areas and submitted to both chemical and cropping tests.

Naturally there is an overlapping in the secondary group. One cannot distinguish clearly between those plants that can absorb selenium from its naturally occurring source and those that must depend upon its being made available to them. Chemical analyses have shown that several species of unrelated plant genera are capable of absorbing selenium from naturally occurring seleniferous soils and in amounts to be toxic to livestock. These same species may be perfectly good forages on very lean or selenium-free soils. Unfortunately there is no physical indication as to whether these plants are good or bad. Supplemental field evidence, of course, can be obtained, provided the geological structures that are known to carry seleniferous rocks are recognized. This is a simple matter where formations of importance are exposed, but it is difficult to follow through completely.

Asters.—Representative species of Asters that have been found to be capable of absorbing toxic quantities of selenium from raw shales include Aster commutatis Gray, A. adscendens Lindl. (fig. 11), A. glaucus T. & G., and A. ericoides L. Range survevs have included several collections of seleniferous Asters believed to be different from the species listed above, but identification was not possible because of the lack of flowers or fruits. The list of seleniferous Asters may, therefore, be considered conservative. The Asters are largely perennials. They propagate easily by means of underground rootstalks. From an economic viewpoint they merit special mention because of their wide distribution, dense growth, palatability to livestock, tolerance to frosts, and adaptability to a variety of climatic and soil conditions. Asters frequently occur in hay meadows. If the soil happens to be seleniferous, the toxic Asters are cut along with the hay. In addition to this, the hay also may be toxic if it has absorbed readily available selenium. This influence of Asters is in no way restricted to meadow lands; on some grass ranges the seleniferous Asters occur in dense growth and markedly affect the associated palatable forages.

Machaeranthera.—The principal species considered in this genus is M. ramosa A. Nels. It is a biennial. On a moderately seleniferous soil this species has yielded as high as 1600 parts per million of selenium. The soil from which this particular collection was taken was found to contain 2.08 ppm. in the first foot, 2.56 ppm. in the second foot, and 7.23 ppm. selenium in the third foot. The basal leaves of M. ramosa are succulent and very palatable. Other species have not been investigated.

Sideranthus grindelioides (Nutt.) Rydb. (Aplopappus nuttallii T. & G.).—S. grindelioides has been found to be definitely seleniferous when associated with soils containing naturally occurring selenium. This and related plants are grazed by sheep during the fall and winter months. While not as seleniferous as Machaeranthera ramosa on the same

general soil types, S. grindelioides and other species are to be considered as possible poisonous plants. In addition, their density of growth is such that a considerable amount of available selenium reverts to the soils in which they grow. Favorable moisture conditions in the fall of the year result in the development of new basal leaves that remain green and attractive to grazing livestock.

Grindelias.—The Grindelias as a group are hardy biennials and perennials. For the most part they are unpalatable. Being prolific seed producers, new stands quickly occupy waste places and abandoned fields. Their selenium absorbing properties are indefinitely established. From the analysis of a large number of collections from such soils as are known to be definitely seleniferous, it is believed that the Grindelias do not absorb selenium to any marked extent from raw shales and soils. Our opinion is that some selenium derived from other plants has to be available to them in order to be absorbed in toxic amounts. Probably G. squarrosa has received more attention than any other species in the genus. Because so many samples taken from seleniferous soils have given negative tests for selenium, the authors have concluded that the species of Grindelias so far examined are not dependable in their selenium absorbing properties.

Atriplexes.—Atriplex canescens and A. nuttallii are representative species that may be seleniferous. As in the case of the Grindelias it is not possible to make clear-cut statements that will prevail over a wide set of conditions. A. canescens has been found to be somewhat more dependable as a selenium absorbing plant than A. nuttallii under the same soil environments. In either case a number of inconsistencies have been observed. It seems quite certain that to absorb enough of the mineral to be significant, A. nuttallii requires a soil that carries some easily available selenium. A. canescens, however, has been found to be a dependable absorber on soils of Pierre and Niobrara origin. From other types of soils the data are too variable to permit definite conclusions at this time. Atriplex pabularis, A. argentea, and A. confertifolia (shadscale) normally have not been found to be seleniferous.

Grayias.—Grayia spinosa collections from a number of western states have been found to be very lean in selenium. Grayia brandegei collected from an area near Rifle, Colorado, was rather highly seleniferous. Isolated cases of this kind are not dependable, because of the possibility of the plants having been influenced by associated seleniferous vegetation. Further collections will be required to determine the status of the species in this genus.

Mentzelias.—Species in the genus Mentzelia that may be expected to absorb selenium in toxic amounts are exceptional. M. decapetala is likely to be associated with a seleniferous soil. On the other hand, it is not usually high in selenium even on soils highly seleniferous. A large number of species collected from various areas in the western states shows that

the group as a whole is of little importance in so far as selenium absorption is concerned.

Pentstemons.—No attempt has been made to investigate the many species in this genus for their selenium absorbing capacities. P. exilifolius A. Nels. frequently occurs in association with the seleniferous Xylorrhizas, Stanleyas, Oonopsis, etc. The amount absorbed is small at any stage of its growth. The tender basal leaves are palatable to range livestock. Under favorable moisture conditions in the fall P. exilifolius may appear as a regrowth and prove attractive to grazing animals. This species has been collected from a number of areas in Wyoming.

Converter plants.—In Wyoming it is generally recognized that localized areas do occur in which practically every type of plant indigenous to the region is seleniferous. Consequently it is difficult to evaluate adequately the average run of selenium bearing plants when complicating influences are involved. The naturally occurring seleniferous soils of the West, considered broadly, are incapable of supporting seleniferous grasses, farm crops, cereals,

and vegetables unless the selenium is in an available form derived from various native plants. Highly seleniferous plants, both of the primary and intermediate types, are continually contributing to a selenium enrichment in those areas where their density of growth is appreciable. Furthermore it is believed that all seleniferous vegetation contains selenium in an organic form.

Soil selenium, when taken up by plants, becomes orientated into one or more organic complexes. The vegetative phase, then, is characterized as one exerting a positive force in converting soil selenium into an organic form. This is a unified action because all plants termed converters are believed to be producing organically combined selenium. In the aggregate, the millions of tons of seleniferous vegetation annually developed in the western United States mean that a very considerable amount of soil selenium has become organically constituted. For example, an average growth of Xylorrhiza parryi (fig. 12) occurring on a moderately seleniferous soil will yield approximately a pound of selenium

Table 1.\* Stratigraphic section of shale at Canyon Glen Camp Grounds, Provo Canyon, Utah.

a Permission to use the lithological data in this table was given by U. S. Geological Survey.

per acre. A 2,000 acre patch would thus absorb a ton of selenium. All of it would be converted to the organic form in the *Xylorrhiza*.

ORIGIN OF SELENIUM IN SOILS.—Selenium occurrence (3, 5, 8, 11, 12) in rocks has been described in earlier publications. The general conclusion was advanced in these publications that vulcanism had exerted a marked influence. Although the authors were not satisfied with attributing the origin of many seleniferous areas entirely to vulcanism, yet not enough evidence was at hand to clarify questionable cases. As our investigations were continued, it became evident that seleniferous soils occurred in a number of states where vulcanism, if present at all, must be considered in a broad manner. Rocks of late Mississippian or early Pennsylvanian age (Carboniferous) have been studied in several areas. A particular shale formation in Provo Canyon, Wasatch Mountains, Utah, is one case in point. The carbonaceous beds in this formation are very seleniferous (table 1). This formation is among the most highly seleniferous geological formations in the western United States. Although the extent to which it supports seleniferous plants has not been determined, a sample of Aster glaucus taken from one of the beds was found to be seleniferous.

An inspection of the data in table 1 shows that the selenium is concentrated primarily in the carbonaceous shale. The selenium in the limestone rock is low. The carbonate content, was found to vary roughly in inverse proportion to the selenium present. Consequently the rocks having the most carbonate contained the least selenium. This relationship suggests that the selenium concentration in this formation is more closely related to the carbon cycle (plant) than to the carbonate.

There is no evidence that volcanoes were active in the region during the time this formation was laid down. The question arises as to the source of the selenium in the beds of this formation: Did it come from igneous rocks by erosion and transport of seleniferous materials? Was there absorption of selenium from the brackish waters by marine organisms and subsequent accumulation on the floor of the sea? Did plants of high selenium-absorbing properties growing in shallow basins and on flood plains become incorporated in the sediments? These are a few of the possibilities that suggest themselves.

The limestones of Pennsylvanian age in southeastern Nevada, the localized caliche-like deposits in southern Arizona and California and the limestones (Carboniferous) in central Idaho are other examples of rocks that not only show a seleniferous composition but are capable of supporting selenium bearing vegetation. Other influences than vulcanism may have contributed to the selenium enrichment in rocks during past geological periods.

Several kinds of selenium enrichment are in evidence at the present time. For the most part our data have been obtained from native vegetation rooted in soils. Very little information has been ad-

vanced concerning plants growing in streams, lakes, and seas. An aquatic plant (water cress) rooted into the water of Warm Springs Creek, Lemhi County, Idaho, showed upon a chemical analysis 16 parts per million selenium. The selenium content of the water was so meager that a chemical test failed to indicate its presence. When viewed as operating over a period of years, it is clear that aggregate plant developments of this kind would gradually find their way to adjacent soils or would become a part of the sediments in stream channels and drainage basins.

Seleniferous rocks, regardless of the geological formation with which they are identified, hold the selenium in a highly insoluble form. In addition to the laboratory evidence on this point it is known that the number of native plant species that can absorb selenium from the raw rock and shales is small compared with the total forage cover indigenous to any seleniferous area.

QUANTITATIVE SELENIUM ANALYSES.—Exploratory studies of seleniferous vegetation in the western states have brought out several significant points in regard to the interpretation of selenium analyses. In many instances a quantitative result may be correctly obtained and reported, but as representing the actual selenium content of a particular plant in situ or over any considerable area it may have merely qualitative significance, and then only for a particular stage of growth, which may or may not be the phase with the maximum amount of selenium.

Within a comparatively small area (table 2) there may be variations of such magnitude in the selenium content of the same species of plants that it would be hopelessly confusing to give a single value as representing the actual selenium relationships of the area as a whole. A review of the data from a detailed study of a typical seleniferous shale formation shows how easily one can be misled in results if sampling is confined to a few samples taken at random. The area chosen for critical study was on a Niobrara outcrop with associated talus and wash. Three stations were established. Station 1 (fig. 13) was in an area designated as wash about one-half mile from the main outcrop. Station 2 was an intermediate station. Station 3 was on the raw shale proper or escarpment. Composite collections of

Table 2. Variations in selenium content of plants growing within a small area.

ation 1	Station 2	Station 3
23	44	47
330	1614	2590
a	1642	860
300	253	135
	67	161
664	883	3250
1190	244	1252
	330 a 300  664	330 1614 a. 1642 300 253 . 67 664 883

<sup>&</sup>lt;sup>a</sup> Blank spaces indicate that representative material was not available.

plants indigenous to the general area were made on the same day in September from all three stations. The samples were analyzed while still fresh. The results are reported as parts per million of selenium on a bone dry basis.

Soil samples were taken at certain depths at stations one and three. The results given in table 3 show the selenium content of the soils at each foot level to a depth of four feet.

Table 3. Soil analyses.

Depth		Station 1	Station 3			
0"-12"	8.1	ppm. Selenium	20.4 ppm. Selenium			
12"-24"	6.8	ppm. Selenium	15.8 ppm. Selenium			
24"-36"	2.9	ppm. Selenium	11.7 ppm. Selenium			
36"-48"	7.7	ppm. Selenium	8.4 ppm. Selenium			
48"-60"			7.8 ppm. Selenium			

These soil analyses show very clearly that a highly seleniferous condition exists in this particular area. Furthermore the surface samples from station 3 are shown to be from two to three times as seleniferous as those from station 1. Yet the data on the selenium in the plants do not suggest this marked difference. These results also show how misleading it is to take a sample of the surface soil and expect that it will represent the selenium content of the lower soil in which the plants are rooted.

If an analysis were to be made of the same plant species as given in table 2 at some other stage of growth, particularly in the initial phases, one would find a greatly increased amount of selenium in all of them with the exception possibly of *Oonopsis*. Whether or not the same distributional relationships would prevail at the three locations could not be conjectured.

When seleniferous native range plants are permitted to dry out before a selenium analysis is made, the loss of selenium will be appreciable in some cases and negligible in others. Fresh samples of Astragalus bisulcatus, A. scobinatulus, A. haydenianus, and

A. racemosus have been found to lose more selenium upon drying out than A. pectinatus at the same general stage of growth. Loss of selenium through drying has not been found to be proportional to the concentration of selenium in Astragalia. Astragalius racemosus and A. bisulcatus were found upon drying to lose about the same amount, whether moderately or highly seleniferous.

### SUMMARY

This paper treats the geographical and geological occurrences of 32 species of native selenium indicator plants, one or more of which are known to occur in twelve western states. Native selenium indicator plants are defined as those which contain significant amounts of selenium during all or a major part of their annual growth and thrive only in rocks or soil which contain selenium. The paper also treats a number of intermediate selenium-bearing plants. These intermediate plants may contain selenium when rooted in selenium-bearing rocks and soils. They are not restricted, however, to such occurrences. The data presented set forth the following: selenium is not a constituent of all rocks; the amount of selenium absorbed by a given species varies greatly at different horizons within a given formation; the areas containing seleniferous plants in which the selenium is present in toxic amounts are limited; a very significant percentage of the vegetation growing on seleniferous soils does not absorb selenium in toxic amounts; seldom are indicator plants formed above an elevation of 8500 feet; all species of Stanleya, Oonopsis, and Xylorrhiza thus far studied are classed as indicator plants; only those species of Astragalus which occur in five of the 29 groups as classified by Jones are seleniferous; the characteristic odor given off by some seleniferous Astragali is evidence that selenium is present. The origin, form, and distribution of selenium in soils is considered.

### INFLUENCE OF GROWTH SUBSTANCES ON GROWTH AND CELL DIVISION IN GREEN ALGAE $^{\scriptscriptstyle 1}$

Melvin A. Brannon and Alfred F. Bartsch

THE FIRST report of the effect of growth substances on algae was made by Yin (1937). In his tests with Chlorella vulgaris he found no measurable increase in the rate of multiplication, but he did find slight increases in size of cells in cultures treated with heteroauxin. At about the same time a report of the effect of heteroauxin on Chlorella miniata, C. pyrenoides (pyrenoidosa?), Cystococcus cohaerans, Oocystis naegelii, and Scenedesmus flavescens was published by Leonian and Lilly (1937). They concluded that heteroauxin is a growth-inhibiting rather than a growth-promoting substance so far as concerns the organisms they studied. Evidence was offered in a preliminary report (Brannon, 1937) of the stimulatory effect of growth substances on Chlorella vulgaris, C. pyrenoidosa, and Oocystis sp. Pratt (1938) offered additional evidence to show that chemical growth substances, including heteroauxin, cause an increase in the rate of multiplication in Chlorella vulgaris. He, however, was unable to confirm Yin's statement that heteroauxin causes an increase in size of cells.

Growth substance studies with vascular plants have probably been emphasized in the past because in these plants correlations, formation of organs, tropisms, and modifications of growth may be studied to better advantage than in algae. In dealing with vascular plants the concentration of growth substance must vary as the solution diffuses through tissues intervening between the point of application and that at which the effects of the applied growth substance are to be studied. This view is supported by Hamner and Kraus (1937) in connection with their histological study of bean plants treated with applications of indole-acetic acid in lanolin. If, instead of using lanolin, the growth substances are injected into the underlying tissues or applied superficially after removing the overlying tissues, the factor of traumatism is introduced. On the other hand, unicellular algae may be immersed in solutions containing known concentrations of growth substance, and the results of such treatment should indicate the effects of the concentration in question. In both cases, however, the concentration of growth

<sup>1</sup> Received for publication October 21, 1938.

The work reported in this paper was conducted for three years in the botanical laboratories of the University of Wisconsin. Grateful acknowledgment is made of the many courtesies received from Dr. E. M. Gilbert, chairman of the Department of Botany. Dr. A. J. Riker, Dr. Winston Manning, Dr. Charles E. Allen, and Dr. John T. Curtis also gave many helpful suggestions and criticisms. We are indebted to Dr. P. W. Zimmerman of the Boyce Thompson Institute for Plant Research for valuable advice and for the initial growth substances used.

The Wisconsin Alumni Research Foundation generously supported this work with grants for two years.

substances which enters into the cells is still unknown.

Bonner (1934) has pointed out that the magnitude of growth substance effects is directly related to the hydrogen-ion concentration of the medium in which the growth substance is applied. He concluded from his study with the Avena coleoptile that the growth substance is converted from the form of an inactive salt to an active nondissociated form in the presence of acid buffers. Marmer (1937) also found that the effect of growth substances on the growth of wheat seedlings is related to the pH of the applied solution. She reported that indoleacetic acid is 15,000 times as effective at pH 4.6 as at pH 7.5, indole-butyric acid is 10 times as effective, and indole-propionic acid 20 times as effective. Albaum, Kaiser, and Nestler (1937) found that the penetration of indole-acetic acid into cells of Nitella takes place more rapidly at pH 3.65 than at pH 7.94. On the basis of their results they concluded that the hydrogen-ion concentration affects the degree of dissociation of molecules of growth substance and that heteroauxin enters cells of Nitella in molecular form. Since in algal cultures it is possible to adjust the pH to a definite value, the effects of known concentrations of growth substance may be studied and compared to greater advantage than in the case of vascular plants where the hydrogen-ion relation may become a variable factor.

The present study was undertaken to determine the effect of several growth substances on cell division and cell size in three species of unicellular green

MATERIALS AND METHODS.—Three types of algae which have different growth rates under identical conditions were selected for this study. Chlorella vulgaris Beyerinck was selected as representative of the fast-growing, Coccomyxa simplex (?) of the intermediate, and Mesotaenium caldariorum (Lagerh.) Hansg. of the slow-growing forms. The first named species was selected in accordance with Du Buy's (1936) statement that "it has been proved previously that growth regulators of the auxin type have an effect only on cells which are in the embryonic stage." Went and Thimann (1937) also concluded that "the cells on which the auxins act are of the least differentiated and simplest type." The unicellular algae which possess a stage corresponding to embryonic cells of higher plants are those which, as does Chlorella, reproduce by means of autospores. These spores have exceedingly thin walls and are highly responsive to physical and chemical changes in the medium in which they are immersed. These algae were identified in the Pflan-

[The Journal for April (26: 179-269) was issued May 15, 1939.] American Journal of Botany, Vol. No. 5, May, 1939.

zenphysiologisches Institut of Prof. E. G. Pringsheim at Prague.

To assure purity and freedom from contamination by bacteria and fungi, agar-plate cultures were made, and a single clone was used as the source material for all subsequent work.

The same liquid medium was used in all experiments. It consists of: 1.0 g. potassium nitrate (0.0099 M), 0.5 g. calcium sulfate (0.0037 M), 0.5 g. magnesium sulfate (0.0020 M), 0.25 g. tribasic calcium phosphate (0.008 M), 0.01 g. ferric chloride (0.0006 M), and 1000 cc. distilled water. The tri-basic calcium phosphate was first dissolved separately in 100 cc. of distilled water, and the other salts were dissolved together in 900 cc. of distilled water. The solutions were then boiled, filtered, and mixed.

Alpha-naphthalene-acetic acid, (indole-3)-n-butyric acid, indole-3-acetic acid, beta (indole-3)-propionic acid, and phenyl-acetic acid were used as growth substances. When this work was begun in 1935 they were obtained from Dr. P. W. Zimmerman of the Boyce Thompson Institute for Plant Research and later from the Eastman Kodak Company and from Merck and Company.

Aqueous solutions which were used in our first experiments were abandoned for alcoholic solutions (1 per cent in 95 per cent alcohol) following a suggestion of Dr. Zimmerman that water is a less effective solvent and that aqueous solutions are probably unstable. Successive dilutions of the alcoholic solution were made with the culture medium in order to obtain the following concentrations (table 1).

Ten cc. of medium were then transferred to each cotton-stoppered Pyrex test tube, and the media were then sterilized by autoclaving for 30 minutes at 15 pounds' pressure.<sup>3</sup>

Preliminary tests indicated the optimum pH range for controlled growth of the three algae to be from

 $^{2}$  M = Molal.

<sup>3</sup> Crystalline indole-acetic acid was hermetically sealed in a fused glass tube which was then immersed in culture medium and autoclaved. The tube was later broken, and dilutions were made under sterile conditions. The effect on cell division of indole-acetic acid treated in this way was not significantly different from that which was dissolved in medium and autoclaved.

5.5 to 6.5. Consequently the pH of all the media used was adjusted within this range by the addition of hydrochloric acid or of sodium hydroxide. Determinations of pH were made with the aid of a Beckman glass electrode.

An equal volume of inoculum was introduced into each culture tube with a glass-sealed constant-flow burette so constructed that all air coming into contact with the inoculum was first filtered through sterile cotton. The entire apparatus was sterilized by autoclaving, and the inoculation room was sprayed with mercuric chloride solution.

Throughout the duration of each experiment, which in most cases was 12 days, the growing cultures were agitated for 5 minutes in each hour by an automatically timed, electrically operated vibratory rack on which the tubes were placed. Illumination was supplied by a 200-watt electric bulb placed at a distance of 1 meter from the cultures. The thermostatically controlled temperature of the culture room varied between 24° and 27°C., and at any given

time all the cultures were at the same temperature.

In most cases the cultures were removed from the vibratory rack after a 12-day growth period, and the number of algal cells per cubic centimeter was determined. Because of the large number of cultures to be measured, haemacytometer counts were not always made, but the turbidity measurements were checked against curves calibrated from haemocytometer determinations. Turbidity was measured by determining the light absorption of a 47 mm. layer of culture as indicated by a Photox (Westinghouse Electric Co.) cell and a microammeter. Agreement between turbidity determinations and haemacytometer counts of cells grown in control media and in media containing 10.0 ppm. of indole-acetic acid is shown in table 2.

The experimental results are presented in the graphs and tables which follow. In the graphs the concentrations of the various acids are arranged, in ppm., on logarithmic abscissae; the number of cells, in millions per cc. of culture, are plotted as ordinates. The horizontal line C represents the number of cells, in millions per cc., in the control cultures. The location of each point on the graphs was determined by the average of measurements from at least four replicate cultures.

Results.—Chlorella.—In the first experiment conducted with Chlorella, a single concentration of indole-acetic acid was used, and comparative growth curves were made of the growth substance and control cultures. Series A (fig. 1) includes the control cultures, and series B those growing in media containing 10 ppm. of indole-acetic acid. These two series were grown at culture-room temperatures of 24° to 27°C. for 42 days, and turbidity measurements were made at intervals of 3 days. The graph indicates that from the time of inoculation the cells in the cultures containing the indole-acetic acid were multiplying at a faster rate than those in the control cultures. After 15 days' growth the number of cells in the growth substance series was 224.0 per cent greater than in the control series. After that time the rate of cell multiplication in the control cultures was greater than in those containing the growth substance so that the two curves converged as the growth period increased. The maximum difference in number of cells per cc. between the control and indole-acetic acid cultures occurred between

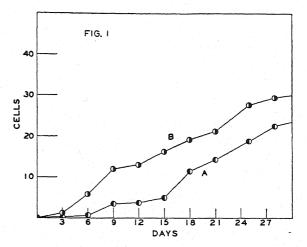

Fig. 1. Growth curve of *Chlorella*. A = Control; B = Series treated with 10.0 ppm. of indole-acetic acid. Number of cells expressed in millions per cc.

12 and 15 days after inoculation. Consequently, in later tests made to determine the optimum concentration of each of the acids, turbidity measurements were made at the end of a 12-day growth period.

In the later tests, 11 concentrations of the five acids were used. The conditions for growth were the same for each test, and all measurements were made at the end of a 12-day growth period. The tests with indole-acetic and naphthalene-acetic acids were conducted at the same time, and the same control cultures were used with both of these test series. The other tests were conducted separately and at different times and consequently had separate controls. The results of these tests are shown in table 3 and in figures 2, 3, 4, 5, and 6.

1. Indole-acetic acid (fig. 2). The optimum concentration of this acid was found to be 10.0 ppm.; and the growth-preventing concentration, 33.3 ppm. The number of cells per cc. at the optimum concentration was 119.0 per cent greater than that of the control. In a concentration as low as 0.10 ppm., the number of cells per cc. was 15.0 per cent greater than that of the control.

2. Naphthalene-acetic acid (fig. 3). The optimum concentration of this acid for cell multiplication was 3.33 ppm., and the growth-preventing concentration

Table 3. Comparison of effect of five different acids upon reproduction in Chlorella after a 12-day growth period. G.P.C. = growth-preventing concentration.

	Millions or	f cells per cc	. of culture	Acid con- centrations in ppm.	Increase, optimum over

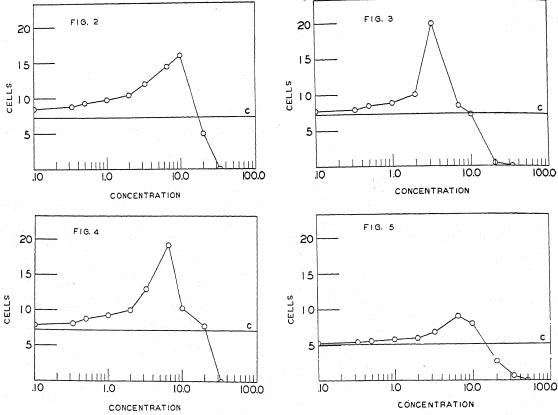

Fig. 2-5. Multiplication of *Chlorella* in several concentrations of different growth substances. Acid concentrations in ppm.; number of cells in millions per cc.; horizontal line, *C*, represents control.—Fig. 2. Indole-acetic acid.—Fig. 3. Naphthalene-acetic acid.—Fig. 4. Indole-butyric acid.—Fig. 5. Indole-propionic acid.

was 33.3 ppm. In the optimum concentration the number of cells per cc. was 172.4 per cent greater than that of the control, and there was no significant stimulation by a concentration of 0.10 ppm.

3. Indole-butyric acid (fig. 4). The optimum concentration for cell multiplication was 6.7 ppm.; the growth-preventing concentration, 33.3 ppm. At the optimum concentration there were 166.5 per cent more cells per cc. than in the control. The stimulatory effect of a concentration of 0.10 ppm. was probably not significant.

4. Indole-propionic acid (fig. 5). The optimum concentration was found to be 6.7 ppm.; the growth-preventing concentration 50.0 ppm. There were 73.1 per cent more cells per cc. in the optimum concentration than in the control, and the effect of 0.10 ppm. on the rate of multiplication was not significant.

5. Phenyl-acetic acid (fig. 6). The optimum concentration was 33.3 ppm.; the growth-preventing concentration, 100 ppm. At the optimum concentration the number of cells per cc. was 261.4 per cent greater than that of the control, and the effect of 0.10 ppm. was not significant.

The order of maximal effect of these five acids is, in decreasing order: (1) phenyl-acetic acid, with an increase of 261.4 per cent over the control; (2) naphthalene-acetic acid, with an increase of 172.4

per cent; (3) indole-butyric acid, with an increase of 166.5 per cent; (4) indole-acetic acid, with an increase of 119.0 per cent; (5) indole-propionic acid, with an increase of 73.1 per cent. The optimum concentration of these acids ranges from 3.33 ppm. for naphthalene-acetic acid to 33.3 ppm. for phenylacetic acid; the growth-preventing concentration ranges from 33.3 ppm. for naphthalene-acetic acid to 100 ppm. for phenyl-acetic acid. Of the five acids, indole-acetic is the only one that caused significant stimulation in a concentration as low as 0.10 ppm. (table 3).

It was reported by Yin (1937) that applications of indole-acetic acid caused increases in the size of cells of C. vulgaris. In the present study, measurement of more than 1,200 cells of C. vulgaris indicated that the mixture of autospores, germinating autospores, and adult cells made it impossible for us to secure reliable data respecting the effect of a growth substance upon the size of cells. In addition, the fact that the cells range from only about 5 to 10 microns in diameter makes accurate measurement extremely difficult. Recently Pratt (1938) found that "heteroauxin was effective in promoting cell multiplication in Chlorella vulgaris, but it had exerted little, if any, influence on the cell size at the end of approximately three weeks." It is possible,

however, that Yin and Pratt were working with different strains of the alga.

A study of *Chlorella* was made to determine the rate of increase in number of cells after a 4-day growth period (A) and after an 8-day period (B)

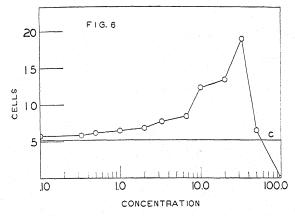

Fig. 6. Multiplication of *Chlorella* in several concentrations of phenylacetic acid. Acid concentrations in ppm.; number of cells in millions per cc.; horizontal line, *C*, represents control.

when the cultures were grown in media containing 11 different concentrations of indole-propionic acid. The results are shown in figure 7 and table 4.

After a 4-day growth period the number of cells per cc. in a concentration of 6.7 ppm. was 16.6 per cent greater than in a concentration of 0.10 ppm. so that different rates of multiplication in different acid concentrations were already evident. During the second 4-day period the number of cells in the optimum concentration of 6.7 ppm. increased 189.7 per cent over that at the end of the first growth period in the same concentration. It can be seen from table 4 that the increase in number of cells per cc. during the second 4-day period over that of the first was greatest in a concentration of 10.0 ppm.; it also shows that the magnitude of increase was progressively less toward the two extremes of concentration. Although the concentration of 6.7 ppm. appears to

be optimum, the number of cells in the next higher concentration (10.0 ppm.) increased 125.0 per cent more rapidly during the second period than did that in the apparent optimum concentration of 6.7 ppm. This indicates that at a later time the highest number of cells would probably be in the higher concentration and that the apparent optimum changes continually until a static cultural condition is reached.

It was found that the response of Chlorella to a growth substance could be both increased and prolonged by agitating the growing cultures, thus facilitating release of autospores from the mother cells and permitting exposure of the autospores to the growth substance. Other effects undoubtedly result from agitation, such as more rapid gas diffusion through the culture medium and the prevention of an accumulation of deleterious substances about the cells. Figure 8 shows the following results of periodic agitation for 12 days: first, the number of cells per cc. was greater in agitated (A) than in nonagitated cultures (B) both in the controls and those containing indole-acetic acid; second, in non-agitated cultures the optimum concentration of indole-acetic acid was 2.0 ppm. with 6,750,000 cells per cc.,

whereas when the cultures were agitated, the optimum was 10.0 ppm. with 19,900,000 cells per cc.; and third, the growth-preventing concentration of growth substance in the agitated cultures was higher (40.0 ppm.) than in the quiescent cultures (20.0

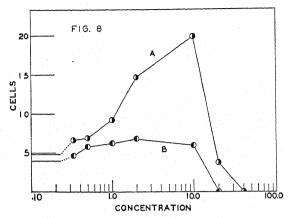

Fig. 8. Effect of periodic agitation upon multiplication in *Chlorella* when grown in media containing several concentrations of indole-acetic acid. A = cultures agitated 5 minutes in each hour for 12 days; B = quiescent cultures. Controls are connected to corresponding series by broken lines. Acid concentrations in ppm.; cells in millions per cc.

ppm.). Hence it is concluded that agitation caused a shortening of the life cycle of the cells of *Chlorella* and also permitted a longer period of growth. It can be seen that the greatest effect of agitation was in the region of optimum acid concentration. The results of this treatment were the same for the five acids.

In studies of the effect of growth substances on vascular plants an interaction has been postulated between the food factor and growth substance factor (Went and Thimann, 1937; Schneider, 1938). It was found (Schneider, 1938) that the addition of both auxin and sugar to the Avena coleoptile, using the section test of Bonner (1933), increased the rate of growth more than the addition of either auxin or sugar alone. Schneider found also that the mag-

nitude of growth increase, when suboptimal concentrations of sugar and growth substance are used, is proportional to the product of the logarithms of the concentrations.

From results obtained by growing cells of Chlorella on agar plates (fig. 9) it appeared that the influence upon the algal cells of the growth substancefood factor interaction is possibly different from that of vascular plants. The colonies shown were selected as typical representatives of each series of cultures. Colonies labeled B were grown for 3 days on agar containing only the inorganic salts used in all the test media, colonies C were grown for the same period on agar containing an addition of 0.10 per cent dextrose, and colonies A were grown on agar containing both 0.10 per cent dextrose and 10.0 ppm. of indole-acetic acid. The effect of 0.10 per cent dextrose upon the size of the algal colonies was as great as or greater than that of the dextrose and heteroauxin together.

Since agar plates are not ideal for physiological experimentation, the test was repeated with liquid media. These media were prepared as follows: (1) containing the inorganic salts alone in the proportions previously described; (2) with an addition of 10.0 ppm. of indole-acetic acid; (3) with an addition of 0.10 per cent dextrose; (4) addition of both 10.0 ppm. of indole-acetic acid and 0.10 per cent

dextrose; (5) addition of 0.25 per cent dextrose; (6) addition of both 10.0 ppm. of indole-acetic acid and 0.25 per cent dextrose.

Media of the 6 kinds were inoculated with cells of *Chlorella*, and the cultures were maintained under constant cultural conditions for 12 days. The number of cells per cc. was determined for each series of cultures at intervals of 3 days. The results of this test are shown in table 5.

The following indications may be shown by the statistical data expressed above: (1) all the test cultures show marked stimulation over the control for a given column (i.e., after 3, 6, 9, and 12 days' growth); (2) there is no significant difference between the stimulation produced by 0.10 per cent dextrose and that produced by 10.0 ppm. of indoleacetic acid plus 0.10 per cent dextrose for a given column; however, there is a tendency for greater stimulation by 0.10 per cent dextrose alone; (3) there is a marked tendency for greater stimulation by 0.25 per cent dextrose than by 10.0 ppm. of indole-acetic acid plus 0.25 per cent dextrose; (4) there is also a marked tendency for 10.0 ppm. of indole-acetic acid plus 0.10 per cent dextrose to produce greater stimulation than 10.0 ppm. of indoleacetic acid plus 0.25 per cent dextrose during the first 9 days with comparatively lesser stimulation from the ninth to the twelfth day; this suggests that inhibitory effects possibly result from the presence of too high a concentration of dextrose and that the effect of the indole-acetic acid does not become evident until the inhibitory effects of the dextrose are overcome; (5) further evidence for the conclusion that 0.25 per cent dextrose exerts inhibitory effects in the early stages of incubation is shown by the fact that the stimulation produced by 0.10 per cent dextrose was greater than that produced by 0.25 per cent dextrose (with or without the presence of 10.0 ppm. of indole-acetic acid) after 3 and 6 days' growth, with no significant difference after 9 days, and with greater stimulation by 0.25 per cent dextrose after 12 days.

These results are in agreement with those of Schneider (1938) only in so far as the stimulatory effect resulting from a combination of dextrose and growth substance is greater than that produced by the growth substance alone. On the other hand, the stimulation resulting from the combination is less than that produced by the dextrose alone. Since a wide range of dextrose concentrations was not used, the effect of sub-optimal concentrations was not determined. It is possible that with such concentrations the interaction of the two factors would produce a similar effect with algae as with vascular plants.

Coccomyxa.—The second alga tested was Coccomyxa. Because of the slow rate of growth of this species, the period of experiment was lengthened to 24 days—twice that allowed for the tests with Chlorella. The lengthening of the growth period accentuated, in the various cultures, differences which perhaps originated in response to certain uncon-

trollable factors such as small variations in volume of inoculum introduced into each tube, differences in handling glassware prior to starting cultures, or possibly to different rates of gas diffusion through the cotton plugs with which the tubes were stoppered. In spite of such variations, the results indicate that suitable concentrations of the five acids tested do exert a stimulatory effect upon the reproduction of the cells of this species. A single graph (fig. 10) is given to show the reaction of this alga

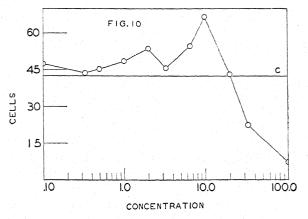

Fig. 10. Multiplication of Coccomyxa in several concentrations of naphthalene-acetic acid. Acid concentrations in ppm.; cells in millions per cc.; horizontal line, C, represents control.

to applications of naphthalene-acetic acid; the results are shown in table 6.

It can be seen that the optimum concentration of naphthalene-acetic acid for reproduction of this species was 10.0 ppm. and that the concentration that prevents growth was not determined, since the cells were still multiplying in a cencentration of 100 ppm. The stimulatory effect of the growth substance resulted in the presence, at the end of the experimental period, of 56.3 per cent more cells than in the control. It is to be noted that this alga is more tolerant of higher concentrations of the growth substances than is *Chlorella*. The optimum concentration of each growth substance for the multiplication of *Coccomyxa* is also higher than that of the same growth substances for multiplication of *Chlorella*.

No evidence was found to indicate that any of the growth substances exerts any influence on the size of cells of Coccomyxa.

Table 6. Influence of naphthalene-acetic acid upon reproduction in Coccomyxa. G.P.C. = growth-preventing concentration.

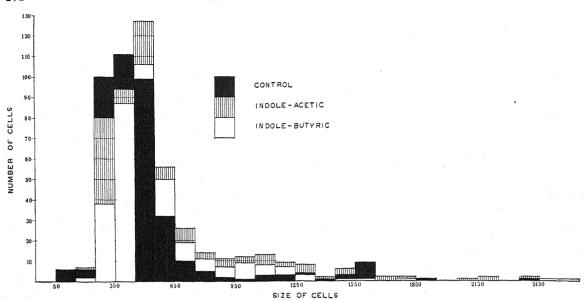

Fig. 11. Comparison of cell sizes of *Mesotaenium* when grown in control media and in media containing either 0.10 ppm. of indole-acetic acid or 0.10 ppm. of indole-butyric acid. Cell sizes expressed in relative volumes. One cell in indole-butyric acid, not shown in figure, reached a size of 5,250 cu. units.

Mesotaenium.—In tests conducted with Mesotaenium the results at the end of a 36-day growth period indicated that each of the 11 concentrations of the 5 growth substances is either inhibitory or at least does not stimulate reproduction. Consequently, an experiment was conducted to determine if any effect upon the size of cells is produced.

Cultures of the alga were made in control media and in media containing 0.10 ppm. of indole-acetic acid in one series and a like concentration of indole-butyric acid in another. The cultures were grown for 4 days before cells were withdrawn for measurement. The cells were measured by the method of Sherbakoff (1927), in which cover-glass smears are placed on thin sheets of agar on microscopic slides, the agar sheet preventing movement of the cells while being measured. A microscope was arranged so that the image, enlarged to a diameter of 100 cm., could be projected on a sheet of white paper 100 cm. square. Outlines of all the cells in any field were drawn on the paper and measured. A total of 1,229 cells was measured and their volumes calculated.

Statistical analysis of the data obtained in this way indicates that there was no significant increase in cell size following treatment with either indole-acetic acid or indole-butyric acid. It is shown by figure 11, however, that there is a tendency for cells treated with the two acids to attain greater relative volumes than those not treated. The figure is arranged as follows: (1) cell volumes are arranged in classes with value intervals of 100 cu. units; (2) the length of a given column represents the number of cells falling into the class in question; (3) the longest of the three columns for a given class is placed in the background and the shortest in the foreground.

Discussion.—Inasmuch as the results reported in this paper show variations from reports of previous workers, it becomes necessary to make a comparison of the techniques employed.

The research of Leonian and Lilly (1937) was based upon a study of "about one hundred different fungi, seven different green algae and corn seedlings." They say in their summary that without a single exception the "higher" concentrations of heteroauxin proved toxic and that the "lower" concentrations failed to produce any stimulation of the algae. The results reported here relative to the toxicity of higher concentrations of heteroauxin (33.3 ppm. and higher) are in entire agreement with toxic results reported by them.

Their conclusion that heteroauxin is a growth-inhibiting rather than a growth-promoting substance has not been confirmed by our experiments. This disagreement is probably due to the following factors: (1) there may have been a widely different pH factor employed in the two studies; no mention was made of the pH used in their tests; (2) they used 0.5 per cent dextrose in their culture media, whereas in the present study it was found that a combination of one-fifth that concentration with 10.0 ppm. of indole-acetic acid produces less stimulation in *Chlorella* than the dextrose alone. It should be men-

<sup>4</sup> In attempting to explain the differential effects produced by dextrose and by a combination of heteroauxin and dextrose, it was found that no qualified conclusion can be made at the present time. Consequently, the following suggestion is offered as a possible explanation. The growth of algae in solutions containing sugar is at least partially heterotrophic, as shown by the experiments of Emerson (1929). It seems possible, then, that the effect of heteroauxin on such plants—namely, inhibition—might be superficially of the same nature as that produced by heteroauxin on fungi which are normally heterotrophic.

tioned in support of this second point that Yin's (1937) report that heteroauxin does not stimulate reproduction in *Chlorella* was based on cultures grown in media which contained sugar, as is indicated by the pertinent literature (Emerson, 1929). On the other hand, the media used in the experiments reported by Pratt (1938), who found, like the present authors, that indole-acetic, indole-butyric, and indole-propionic acids act as stimulators for *Chlorella*, contained no sugar except when the effect of sugar itself was being tested.

The differences in effect of the growth substances on Coccomyxa and Chlorella are possibly due to the facts that the cells of the former are surrounded by a gelatinous matrix and that they reproduce by division into only two cells. These facts may explain the slower rate of growth and the complications which resulted in all experiments involving this species.

From tests which were conducted with Chlorella and Mesotaenium it became apparent that under normal conditions the cells of the former reproduce much more rapidly than those of the latter. The methods of reproduction involved illustrate the reason for this difference. The cells of Chlorella develop and liberate a set of four or more autospores at intervals of about one hour, whereas the cells of Mesotaenium divide into two once in about 12 hours -that is, Chlorella reproduces about 25 or more times as fast as Mesotaenium. It has been pointed out, with support from the work of Pratt (1938), that applications of heteroauxin that stimulate reproduction in Chlorella cause no apparent effect upon the size of cells. This was found to be true of 12-day-old cultures in which the heteroauxin had not been entirely inactivated as indicated by experiments in which the cultures were centrifuged and the supernatant liquid autoclaved and reinoculated. It has been shown by Yin (1937), however, that heteroauxin did affect the size of cells in his cultures. There are two possible reasons for this disagreement: first, different culture media were used in the three studies; and second, different strains of *Chlorella* may be involved.

### SUMMARY

The effects of five monobasic organic acids upon reproduction and cell size in three species of unicellular green algae have been investigated.

Suitable concentrations of naphthalene-acetic, indole-acetic, indole-butyric, indole-propionic, and phenyl-acetic acids, applied in sugar-free inorganic culture media, stimulated reproduction in *Chlorella vulgaris* and *Coccomyxa simplex* but not in *Mesotaenium caldariorum*.

The five acids exerted no measurable influence upon the size of cells in either Coccomyxa or Chlorella, but indole-acetic and indole-butyric acids caused a tendency for cell enlargement in Mesotaenium.

A possible explanation is offered for the different results obtained with the three species of algae.

Evidence is presented to indicate that the interaction of the growth substance factor and the food factor for algae is probably of a different nature from that reported for vascular plants.

### THE SHAPE OF COMPRESSED LEAD SHOT AND ITS RELATION TO CELL SHAPE <sup>1</sup>

James W. Marvin

Studies of the shape of undifferentiated cells as they occur aggregated into tissues have heretofore often emphasized the rôle of surface tension as a significant physical factor in determining the form of such cells. But, pressure relations between cells, such as parenchyma, aggregated without large intercellular spaces, are also important in shape determination. Experiments were therefore devised for using spheres in a physical system in which surface tension is reduced to a minimum. Small lead shot of uniform diameter were compressed in a cylinder until all the interstices were eliminated, and the shapes of the polyhedra produced by such compression were studied.

Early investigators were impressed with the angular and frequently hexagonal appearance of cells in cross section, and Kieser (1815), considering the three-dimensional shape of parenchymal cells, believed them to be fundamentally rhombic dodecahedra. These figures, with twelve quadrilateral faces of equal size, each have six tetrahedral and eight trihedral angles. Rhombic dodecahedra of uniform size will aggregate to fill space without interstices, and this type of polyhedron may be produced by the compression of uniform spheres regularly stacked, twelve in contact with a central one.

Later, the work of Berthold (1886) and Errera (1887) emphasized the importance of surface tension in cellular systems. Lord Kelvin (1887), after experimenting with liquid film systems, suggested an orthic tetrakaidecahedron as an economical surface-volume configuration having trihedral angles and permitting the division of space without interstices. This figure has eight hexagonal and six square faces; all the edges of the faces are equal; and the surface area of the figure is slightly less than that of a rhombic dodecahedron of equal volume. The orthic tetrakaidecahedron has trihedral, but no tetrahedral angles. The six tetrahedral angles which occur in the rhombic dodecahedron are unstable in a liquid film system.

The first extensive studies of cell shape in three dimensions are the outstanding contributions of Lewis (1923, 1925, 1928, 1930, 1933). He found that cells in undifferentiated tissues in a number of plants and animals are fundamentally fourteen sided, sometimes approaching in shape the orthic tetrakaidecahedron.

METHOD.—In the studies outlined below lead shot of two diameters, 1.27 mm. and 2.54 mm., were used. They were examined under a binocular dissecting microscope, and the asymmetrical ones were discarded. The shot were compressed by means of a

1 Received for publication January 13, 1939.

It is a pleasure to acknowledge the stimulating suggestions and advice of Professor E. B. Matzke under whose direction this work was carried out.

steel plunger in a steel cylinder with a bore 25 mm. in diameter and 75 mm. long.<sup>2</sup>

After compression the shot were studied under a binocular dissecting microscope by means of a mechanical manipulator. This instrument consists of two curved steel needles fitted to a pair of mechanical forceps which can be made to open and close. The forceps are in turn attached to a system of geared adjustments in such a manner that the needles, after picking up a lead ball, can be rotated on a horizontal axis or moved up and down or from right to left in the horizontal field of the microscope. With this device it was possible to study all the faces of a polyhedron in sequence. With slight modification, this manipulator can also be used in studying the shape of cells (Marvin and Matzke, 1939).

To aid in determining the effect of the position of a shot in the cylinder on its number of faces, an ocular guide was constructed. It consisted of two concentric rings so placed that the cross sectional area of the cylindrical mass of shot was divided into three regions. These regions were of approximately equal radial dimension and were about 4.17 mm. wide.

Data.—In the first experiment, shot 2.54 mm. in diameter were used. These shot were poured into the cylinder and compressed at pressures varying from 1,000 to 35,000 pounds. As the result of several trials, 35,000 pounds pressure on the plunger, when applied at the rate of 0.1 inch per minute, was found sufficient to eliminate all the interstices between the shot, to cause them to aggregate, and to form a cylinder of coherent shot whose individual members were easily separated.

The results of these compressions are given in table 1, figures 1-7, and figure 9. Figures 1-7 are photographs of the shot as they appear in the cylinder after compression. Figure 1 shows that flattening occurs at the points of contact as the result of 1,000 pounds pressure. A pressure of 2,500 pounds

Table 1. The average number of contacts observed on lead shot compressed at different pressures.

35,000 lbs.	100	14.16

<sup>&</sup>lt;sup>2</sup> These compressions were made possible by the generous and helpful cooperation of Mr. J. N. Kenyon of the Research Laboratories of the Department of Civil Engineering of Columbia University.

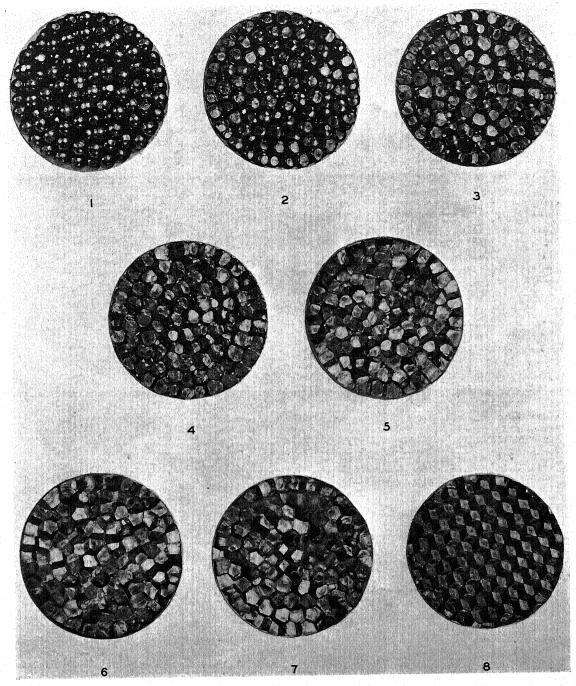

Fig. 1-8.—Fig. 1-7. Photographs of the effect of different pressures on the compressed lead shot of the larger size used (2.54 mm. in diam.).—Fig. 1. 1,000 pounds pressure.—Fig. 2. 2,500 pounds pressure.—Fig. 3. 5,000 pounds.—Fig. 3. 5,000 pounds.—Fig. 4. 7,500 pounds.—Fig. 5. 10,000 pounds.—Fig. 6. 22,500 pounds.—Fig. 7. 35,000 pounds.—Fig. 8 shows the appearance of the shot after compression when stacked in the arrangement to produce rhombic dodecahedra. ×9/5.

produces some faces larger than those seen in figure 1, while new contacts resulting from the additional pressure have produced small faces (fig. 2). This introduction of new faces, from additional contacts due to increasing the pressure, also occurs in figures 3, 4, 5, and 6, while in figure 7 all the

spaces between the shot have been eliminated, and no new contacts can occur. The number of facets has reached its maximum.

Table 1 gives the average number of faces observed on one hundred shot, the number examined at each pressure. These shot were selected at ran-

dom from the cylinder, but they do not include any from the peripheral layer. After being submitted to 1,000 pounds pressure, the shot had an average of 8.41 contacts; at 2,500 pounds, the average was 8.55 contacts per shot, slightly more than that observed at 1,000 pounds. With each increase in pressure, there was an increase in the average number of contacts—namely, at 5,000 pounds, an average of 10.97 contacts, at 7,500 pounds, an average of 11.61, at 10,000 pounds the average was 12.91, and at

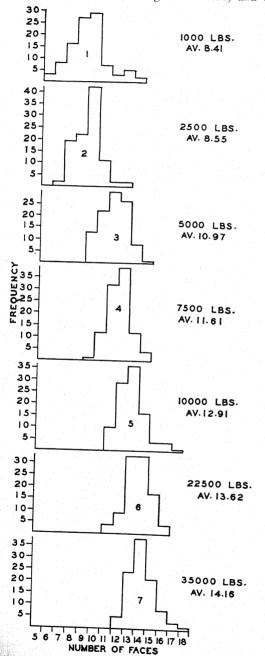

Fig. 9. Histograms of the number of faces on lead shot compressed at varying pressures.

22,500 pounds it was 13.62. At 35,000 pounds all the spaces between the shot were eliminated, and the polyhedra produced by this compression averaged 14.16 faces. This has been previously reported in summary form (Marvin, 1937).

Figure 9 presents the range in the number of faces on the shot examined at each pressure. For figure 9, no. 1, the range is from shot with five contacts to those with thirteen, with a poorly defined mode at 9 contacts per shot. At 2,500 pounds the range becomes somewhat narrower, six to twelve contacts per shot, with a well-defined modal class at nine (fig. 9, no. 2). As the pressure increases up to 35,000 pounds, there is a marked increase in the number of contacts per shot, with the range in the number of contacts remaining very nearly the same at each succeeding pressure—namely, six or seven. The range for each histogram does not include the range for the series, but as the pressure is increased, the relative position of the histograms shifts in the direction of more contacts per shot.

Experiment 1 indicates that after shot are poured into a cylinder, there are approximately eight points of contact between shot (these contacts may be called "primary"), and as the spaces between the shot are eliminated by pressure, "secondary" contacts occur—that is, additional contacts between shot not in contact at first. With increasing pressure, the number of contacts increases to about 14, when all the interstices are eliminated.

In the second experiment, the large shot, 2.54 mm. in diameter, were placed in the cylinder one at a time in the so-called "cannon ball" arrangement. Here the shot in the first and succeeding layers were placed in parallel rows, and except at the periphery each shot was in contact with 6 others in its own layer. The second layer of shot was placed on the first in such a manner that each shot was supported by three from the first layer, and each member of the third layer was in turn supported by three members of the second layer. Thus it may be seen that each shot (except those at the periphery) in any given layer was in contact with six others of the same layer and was also in contact with three members of the layer above and three of the one below, making twelve contacts in all. The cylinder was filled with shot stacked in this manner and submitted to 35,000 pounds pressure to eliminate all the interstices.

An examination of these shot after compression showed them to be dodecahedra. Perfect symmetry was not achieved, however, for the unilateral pressure caused a slight flattening of the figures and certain of the faces were smaller than the others. Here twelve contacts between shot occurred before compression, and twelve faces were present after all the spaces had been eliminated (fig. 8).

Experiments 3, 4, and 5 are similar in some respects and will be considered together. In an attempt to determine the effect of the position of a shot in the cylinder on the number of its faces, the cross-sectional area of the cylindrical mass of shot

Table 2. Number of faces on lead shot poured into a cylinder and compressed to eliminate all the spaces between the shot. Discussion in the text.

was divided into three regions of equal radial dimensions in each experiment by using the ocular guide previously described. The peripheral layer of the outermost of these three regions was designated as zone A; the remainder of this outermost region was called zone B; the middle region constituted zone C, while the innermost of these regions, containing the shot in the center of the cylinder, comprised zone D. Experiments 3, 4, and 5 differ in the size of the shot used and in the treatment of the shot after being poured into the cylinder. In Experiment 3, the small shot were shaken down after being poured into the cylinder to determine whether or not the number of initial contacts would be changed, thereby possibly altering the number of faces on the shot after compression. In Experiment 4 the small shot were poured into the cylinder but were not shaken down. For Experiment 5, shot 2.54 mm. in diameter, twice the size of those used in Experiments 3 and 4, were used. These large shot were poured into the cylinder and compressed without being shaken down.

One hundred shot were examined from each of zones C and D in Experiments 3 and 4, and one hundred from zones A and B combined. Smaller numbers were studied in Experiment 5. In table 2 the average number of contacts obtained for the shot from the four zones in each experiment are listed. A statistical treatment of the data is given in table 3. In figure 10 frequency histograms are presented showing the range in the number of contacts observed in Experiments 3, 4, and 5, and also a summary of those data.

In Experiment 3 (table 2) in which small shot 1.27 mm. in diameter were poured into the cylinder and shaken down, 37 peripheral shot and 63 from zone B were examined. The peripheral shot had an average of 10.86 contacts; those in zone B, 14.25. One hundred shot from zone C had an average of

14.15 faces, and one hundred shot from zone D averaged 14.09 contacts per shot.

The ranges in the number of contacts for the shot studied from the four zones in Experiment 3 are presented in figure 10. The peripheral layer, 1-A, includes shot with 8 to 14 contacts—a range of 7, with the modal class at 10. Those in zone B, 1-B, have a range of 6, from 12-sided to 17-sided shot. Zones C, 1-C, and D, 1-D, include seven kinds of polyhedra, 11-sided to 17-sided. The last three groups, 1-B, 1-C, and 1-D, all have modes at 14. Thus, zones B, C, and D have very nearly the same range and the same modal class. Their histograms are similar in shape. The histogram of the peripheral shot, 1-A, shows a distribution and a modal class quite different from those of 1-B, 1-C, and 1-D.

In Experiment 4, the small shot, 1.27 mm. in diameter, were poured into the cylinder and compressed without being shaken down. From table 2 it is evident that 39 peripheral shot and 61 shot from zone B were examined. The average for the peripheral shot was 10.82 contacts, while that for zone B was 14.13. The averages for zones C and D were 14.23 and 14.17, respectively.

As shown in figure 10—2A, 2B, 2C, and 2D—the histograms of the data in Experiment 4 are similar to those of Experiment 3—1A, 1B, 1C, 1D. The peripheral shot have a markedly different range and mode from the shot in zones B, C, and D, while zones B, C, and D all show nearly the same range and have the same modal class—namely, 14.

The large shot, 2.54 mm. in diameter, were used in Experiment 5. They were poured into the cylinder and were compressed without being shaken down. In this experiment, in which 30 shot were examined from the peripheral layer, there was an average of 10.57 contacts per shot. From zone B, 18

Histograms of the number of faces on lead shot in Experiments 3, 4, and 5, 1A, 1B, 1C, 1D, histograms for zones A, B, C, and D, respectively, in Experiment 3; 2A, 2B, 2C, 2D, histograms for zones A, B, C, and D, respectively, in Experiment 4; 3A, 3B, 3C, 3D, histograms for zones A, B, C, and D, respectively, in Experiment 5; 4A, summary histogram for zone A in Experiments 3, 4, and 5; 4B, summary histogram for zones B, C, D in Experiments 3, 4, and 5.

shot were examined, and these averaged 14.05 contacts. The 46 shot examined from zone C and the 36 from zone D had averages of 14.17 and 14.19, respectively.

The histograms of the shot studied in this experiment are shown in figure 10—3A, 3B, 3C, and 3D. A range of 7 in the number of faces, 8–14, was observed on the peripheral shot (3A), while the shot from zone B vary in contacts from 12–17, a range of 6. In zone C the spheres were compressed into polyhedra having 12 to 18 sides, a range of 7, and in zone D the range was 4, from 13–16. In Experiment 5 as in Experiments 3 and 4, the peripheral shot have a range and a modal group markedly different from those of the other layers. The range is nearly the same and the modal class is the same for all the deeper layers.

From table 2 it is likewise evident that the averages for zones B, C, and D in each experiment are similar. And further, the averages of these inner zones were essentially the same in Experiments 3, 4, and 5. The data were therefore treated statistically to test the significance of their differences. The ratios in table 3, when interpreted in the light of a table of the areas of the normal probability curve, indicate the chances that the true difference between the means is as great or greater than the observed differences. For approximate analysis a ratio greater than three may be accepted as significant, while one appreciably less than three may be considered not significant. This principle was fol-

<sup>3</sup> It is with pleasure that the helpful suggestions of Professor F. E. Croxton of Columbia University in the statistical treatment of these data are gratefully acknowledged.

lowed here, and it will be observed that all ratios are either much greater or much smaller than 3.

In Experiments 3, 4, and 5 the mean for the peripheral shot in each experiment, when compared with the mean for the layers of zone B in the same experiment, was significantly different; this indicates that the wall of the cylinder has a marked effect on the number of contacts observed for the peripheral shot. Similarly, when the two extreme means for the layers of zone B and for zones C and D (i.e., table 2, Experiment 3, zone D—14.09—and Experiment 3, zone B—14.25) were compared in each experiment, these differences were found not significant. It appears, therefore, that, except for the peripheral shot, the radial position of a shot in the cylinder does not influence the number of contacts it will show after compression.

A comparison of the high and the low means obtained for the peripheral shot in Experiments 3, 4, and 5 showed that here the difference between the two means was not significant. Therefore, using large shot or shaking the shot after it was poured into the cylinder had no significant effect on the number of faces on the peripheral shot. Similarly, the shot from the inner layers comprising zones B, C, and D in these three experiments were compared,

and it was found that shaking the shot after they were poured into the cylinder or using large shot (twice the diameter of the small shot) had no significant effect on the number of contacts produced by compression.

The results for Experiments 3, 4, and 5 were grouped and, as seen in table 2, the 106 peripheral shot had an average of 10.76 contacts, while the 624 inner shot averaged 14.17 contacts or faces.

The frequencies of the kinds of faces found on the compressed lead shot are presented in figure 11 and in table 4. The first histogram (fig. 11) presents the totals of the kinds of faces found on the peripheral shot in Experiments 3, 4, and 5. The totals of all the kinds of faces found on shot from zones B, C, and D in Experiments 3, 4, and 5 are shown in the second histogram. The faces on the peripheral shot range from triangular to octagonal, with pentagonal most common, quadrilateral next, and then hexagonal. The number of pentagonal faces is only slightly less than half the total number of faces of all kinds; there are 495 pentagonal faces and 1141 faces in all. A study of the frequency histogram of the number of faces on shot from zones B, C, and D shows a range in the number of edges on a face from 2 to 9, with pentagonal faces most common, hexago-

nal faces next, and quadrilateral faces third. A face with two edges is possible only if the edges are curved, and this is not common, for in general the edges are straight (fig. 7). The number of pentagonal faces is approximately 3/8 of the total number of faces, since there are 3420 pentagonal faces in a total of 8840. Thus, both in the peripheral layers and in zone B as well as in zones C and D, pentagonal faces are most common.

Table 4 gives the frequency of occurrence of each kind of face, and also a ratio which shows the proportionate occurrence of each kind of face in the peripheral layer, zone A, in Experiments 3, 4, and 5, as well as for zones B, C, and D.

A study of the number of trihedral and tetrahedral angles on 106 peripheral shot in Experiments 3, 4, and 5 revealed 1834 of the former and 12 of the latter. Thus, the proportion of tetrahedral to trihedral angles is 1 to 153. Similarly, in the 624 shot from zones B, C, and D there were 14,866 trihedral angles and 159 tetrahedral angles, or 1 tetrahedral to 93 trihedral angles.

Discussion.—In Experiment 1, the irregular appearance of the lead shot is explained by their random and uneconomical space-filling arrangement. A pressure of 1,000 pounds caused a flattening of the shot at the points of contact between adjacent shot, and a study of these individuals showed the contacts to be irregularly distributed. As the pressure was increased, these first-formed contacts became the large faces with a relatively large number of edges, and when compressed further, new contacts occurred which produced faces smaller than those formed first. There seems to be a direct correlation between the distance between the centers of any two shot which are in direct contact, or which will eventually be in contact after compression, and the size of the resulting faces. In other words, the faces produced from primary contacts normally will be larger than those from contacts induced by pressure.

In contrast with these results are those of Experiment 2 in which shot were placed in the cylinder in cannon-ball fashion and compressed. No new contacts or faces were introduced, and 12 faces,

representing the 12 original contacts, were produced. Shot poured into the cylinder, as in Experiment 1, had fewer than 12 initial contacts, and, after compression, the introduction of new faces from secondary contacts gave a total of more than 12 faces.

In Experiments 3, 4, and 5 the radial position of a shot in the cylinder, except in the peripheral layer, did not cause a significant change in the number of faces produced by compression. Also, neither shaking the shot down after pouring nor using large shot in the cylinder significantly affected the number of faces resulting from the pressure.

In this physical system, in which the lead shot were submitted to pressure in a cylinder whose diameter is approximately 20 times that of the shot, a ratio was established similar to that existing in some plants between the diameter of the pith and that of individual pith cells. In zones B, C, and D in Experiments 3, 4, and 5 the average number of contacts in each case was slightly more than 14. Lewis (1937) has suggested that this excess above 14 is due to the curvature of the tube, the increasing circumference peripherally tending to allow additional contacts. Statistically 14.17 is significantly different from 14, under the conditions here described and if 14 is an ideal figure subject to no variation. This conclusion is based on the relatively large number (624) in our sample. Each of the individual means in table 2-i.e., 14.25, 14.15, 14.09, 14.13, etc.—based on a smaller number of shot is not significantly different from 14 statistically. An average of 14 faces might be realized under ideal conditions. However, the experiments here described are subject to certain limitations such as the unilateral pressure and the relatively large diameter of the shot compared with the diameter of the cylinder, so that the curvature of the cylinder might well have an effect on the number of contacts. Bearing such factors in mind, the striking feature is perhaps not the difference from 14, which is barely distinguishable, but the close approximation to 14 that was actually achieved. When compared with cell data (Lewis, 1923) in which the cells observed had a range from six to twenty contacts, the averages for the 624 shot (14.17) and for the 100 cells (13.96) are not significantly different.

Although the average number of contacts was 14.17, the orthic tetrakaidecahedron, with its 8 hexagonal and 6 square and no pentagonal faces, was not realized in the shot, since the latter had many more pentagonal than either hexagonal or quadrilateral faces. Indeed it has not been found completely realized in plant or animal tissue, in which pentagonal facets are likewise abundant, though there is a recognizable approach to the orthic tetrakaidecahedron in certain cells (Lewis). Thus, the similarity between the shape of cells which are considered deviations from the orthic tetrakaidecahedron and the lead shot exists in the number of contacts and the relatively few tetrahedral angles of which the orthic tetrakaidecahedron has none.

Lewis (1928), studying the shape of the columnar epidermis of cucumber, frequently found these cells to have eleven sides, with 10 contacts between cells and one exposed face. Such cells would have 6 lateral contacts, 4 basal contacts, and one face exposed at the surface. In the study set forth here, 106 peripheral shot averaged 10.75 contacts, and some of the individuals observed had a pattern similar to that described for the epidermal cells. In Experiments 3, 4, and 5 the peripheral layer in each case had slightly fewer than 11 faces. Lewis (1937) again ascribes this difference to the curvature of the cylinder and "the diminished circuit of the row next within" the outermost layer. The average of 10.75 found in the shot is not significantly different statistically from 11 under the conditions of those experiments.

In the experiments on the lead shot presented above, surface tension and the biological factors affecting cells in tissues have not been active, although they are highly important in living organisms. However, the striking agreement in number of contacts between cells in tissues (Lewis) and the lead shot compressed to eliminate interstices indicates that pressure relationships are of prime importance in cell shape determination.

It seems very probable, furthermore, that the intercellular spaces between cells in certain tissues may result as much from pressure relations as from physiological necessity. Cells subjected to relatively low pressure—not necessarily external—may well tend to be rounded and have an abundance of intercellular spaces, while between those strongly compressed, spaces may be small or lacking.

#### SUMMARY

Pressure relations between parenchymal cells have not been emphasized in studies of their shapes. Small lead shot of uniform diameter were compressed, and then examined, to determine the effect of pressure on uniform spheres in a system in which biological factors were not active and surface tension was reduced to a minimum.

Pressures varying from slight to sufficient for the elimination of all the spaces between shot poured into a cylinder gave varying numbers of contacts, from 8.41 with slight pressure to 14.16 when all the spaces had been eliminated. The last figure approximates very closely the average of 13.97 contacts which Lewis found for 250 cells in undifferentiated

The peripheral shot in the cylinder averaged 10.75 contacts per shot, not very different from the 11sided cells of cucumber epidermis studied by Lewis. The 624 shot from the layers other than the peripheral, zones B, C, and D, had an average of 14.17 faces per shot.

The radial position of a shot inside the peripheral layer in the cylinder had no effect on the number of contacts.

Shaking the shot down after they were poured into the cylinder or using shot of twice the diameter had no appreciable effect on the average number of contacts.

The compressed lead shot are not orthic tetrakaidecahedra with 8 hexagonal and 6 square faces, for pentagonal faces are most common, and triangular, heptagonal, octagonal, and nonagonal, as well as quadrilateral and hexagonal faces occur.

The compressed lead shot, like Lewis' cells, had

relatively few tetrahedral angles.

The abundance of intercellular spaces between parenchymal and possibly other cells may result as much from pressure relations between the cells as from physiological necessity.

# VOLUME-SHAPE RELATIONSHIPS IN LEAD SHOT AND THEIR BEARING ON CELL SHAPES <sup>1</sup>

Edwin B. Matzke

Previous work has shown marked and significant similarities in three-dimensional shapes between cells in undifferentiated tissues and compressed lead shot of uniform diameters. Since cells, even in the same tissue, are never identical in size and frequently not uniform, an examination has been made of the shapes of lead shot of two diameters and volumes, compressed so that all interstices were eliminated. The large and small shot were mixed, to simulate cellular conditions in living organisms. A study of the patterns so produced should throw light on the mechanics of cell shape determination.

In 1887 Lord Kelvin wrote a philosophical essay in which he conceived of the division of space into polyhedra each having fourteen faces, eight hexagonal and six square; such figures he called tetrakaidecahedra. Influenced by the earlier work of Plateau (1873) on soap films, he was thinking especially in terms of stability of angles, economy of surface with reference to volume, and stackability. The biological implications of Lord Kelvin's deductions were entirely unappreciated for thirty-six years, until Lewis (1923) published the first of his searching investigations on the three-dimensional shapes of massed cells. These observations have since been extended to diverse kinds of tissues. Considering especially the more undifferentiated tissues of those that Lewis (1923, 1925, 1933) has studied, one hundred elder-pith cells, one hundred human fat cells, and fifty precartilage cells of the tadpole have an average of 13.97 faces—a remarkably close approximation to a fourteen-sided figure. The faces were not exclusively hexagonal and square, however, as would be the case if Lord Kelvin's tetrakaidecahedron were fully realized.

Recently Marvin (1937, 1939) has shown, on the basis of 624 counts, that lead shot of uniform diameter, compressed to eliminate interstices, have an average number of faces also very close to fourteen (14.17). In the number of contacts, then, the compressed lead shot of uniform diameter and the cells of undifferentiated tissues show striking similarity. In addition to hexagonal and square faces, many of those of the lead shot were pentagonal.

The significance of the tetrakaidecahedron in the biological realm has been extended by Glaser and <sup>1</sup> Received for publication January 12, 1939. Child (1937) and by Glaser (1938); it has been considered also from other standpoints by Marvin (1936), Lewis (1937), and Matzke (1927, 1931).

MATERIAL AND METHODS .- The experiments described below were done with patent finish drop shot of two diameters, the "large" shot of approximately 2.54 millimeters (.10 inch), the "small" of approximately 1.27 millimeters (.05 inch). Before being used, each shot was examined under a binocular dissecting microscope magnifying 25 diameters, and those showing imperfections in shape, size, or surface were discarded. The large and small shot in varying proportions were then mixed as uniformly as possible and carefully poured into a steel cylinder having a 25 mm. bore. In each experiment they were compressed by means of a steel piston, from above, with a pressure of 40,000 pounds.2 This was sufficient to eliminate completely the spaces between the shot but permitted their subsequent separation without great difficulty. This pressure made it possible to transfer the compressed shot, in one mass, from the steel cylinder to a glass cylinder, with an inside diameter of 25 mm., fitted with a wooden piston. The shot could then be picked off one by one. The upper and outer several layers were discarded in each case, and the data presented below are based entirely on a study of the inner shot. Each compressed shot was examined under a binocular dissecting microscope magnifying 25 and 50 diameters, being handled by the manipulator constructed by Marvin and previously described (Marvin and Matzke, 1939).

Three compressions were made, using three different proportions of large and small shot. In the first, 5 cc. of the selected small shot and 20 cc. of the selected large shot were mixed, giving a volume ratio of 1 small: 4 large. By number there were approximately twice as many of the small balls as of the large ones. The ratio of small to large shot used in the second compression, by volume, was 1 small: 1 large, 13 cc. of each having been mixed together. There were about eight times as many of the small shot by number as of the large in this experiment. In the third compression the volume ratios were

<sup>2</sup> The compressions were made in the Research Laboratories of the Department of Civil Engineering of Columbia University by Mr. John N. Kenyon, and it is a pleasure to acknowledge his ever generous and willing cooperation.

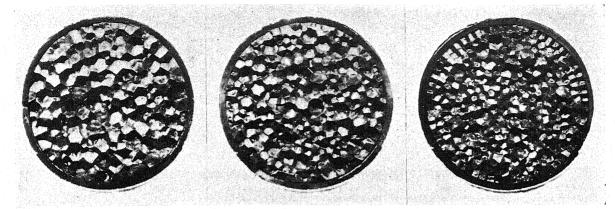

Fig. 1-3.—Fig. 1 (left). Surface view of cylinder of compressed lead shot used in experiment 1. Since the ratio of small to large shot, by volume, was 1:4, the large shot are more conspicuous than the small. The faces on many of the large shot are plainly evident. ×9/5.—Fig. 2 (center). Surface view of cylinder of compressed lead shot used in experiment 2. Equal volumes of small and large shot were used, and compressed shot of both sizes are clearly visible. ×9/5.—Fig. 3 (right). Surface view of cylinder of compressed lead shot used in experiment 3. The ratio of small to large shot, by volume, was 4:1, and consequently the small shot are much more conspicuous, though some of the large ones can also be seen. ×9/5.

4 small: 1 large, 20 cc. of the large and 5 cc. of the small having been used. By number in this third experiment there were approximately 32 small: 1 large.

DATA.—The general appearance of the shot in these three experiments is shown in figures 1, 2, and 3, which are photographs of experiments 1, 2, and 3, respectively. It is evident that the cylinder shown in figure 1 contains the largest proportion of the large shot, while that in figure 3 shows the greatest proportion of small shot. Figure 2 (experiment 2) is intermediate.

The number of faces on the compressed shot and the average number of faces is given in tables 1, 2, and 3. In the first experiment (table 1), in which

the ratio of small to large shot was 1:4, by volume, the number of faces per small shot varied from 6 to 13, with the greatest frequencies at 9 and 10; the average number was 9.5. The data in all the experiments are based on 50 shot selected at random from the central portion of the cylinder. In the case of the 50 large shot tabulated for experiment 1, the number of faces per shot varied from 15 to 24, the greatest number having 19 and 20 faces, and the average being 19.98. Marvin (1937, 1939) found that the average number of faces per compressed shot, with all interstices eliminated, was approximately 14, if all the shot were uniform in size. He

used both the large and small shot here tabulated, and when either was used alone, the average number of faces was about 14. It may be concluded from the data here presented, then, that when the large and small shot are mixed in the proportions indicated, the number of faces on the small shot drops from 14 to about 9.5, while the number of faces on the large shot increases from 14 to approximately 20.

In the second experiment, in which equal volumes of small and large shot were used (13 cc. of each), the number of faces on 50 small shot selected at random varied from 9 to 15, 12 and 13 being the commonest with the average at 12.04. The 50 large shot in this same cylinder showed a range in the number of contacts from 19 to 30, with an average of 25.62, and the greatest frequencies at 24, 25, 26, 27, and 28. In this case the large shot were more frequently in contact with small shot than in experiment 1, and hence the number of contacts on the large shot is greater. The small shot probably were also more frequently in contact with small shot than in experiment 1, since there were more of the small shot in experiment 2, and therefore the number of contacts came closer to 14 than in the first experiment.

In experiment 3 the ratio, by volume, of small to large shot was 4:1, 20 cc. of the small and 5 cc. of the large shot having been used. The ratio in number of shot was approximately 32 small:1 large. The number of faces on the 50 small shot examined varied in this experiment from 10 to 16, 13 and 14 being the most common, with the average at 13.3. In the 50 large shot chosen at random the number of contacts ranged from 25 to 36, with the greatest frequency at 31 and the average at 30.18. Under

the conditions of this experiment, small shot are nearly always in contact with small shot, and consequently the average (13.3) of the small shot comes close to 14, which would have been the average if only small shot had been used. The large shot has more numerous contacts in this experiment than in either of the others, presumably because under these conditions the large shot is surrounded mostly or in some cases perhaps entirely by small shot. If the diameters of the small and large shot are kept at 1:2, increase in the proportion of small to large shot, by volume, would not continue to increase the number of faces on the large shot indefinitely. The large shot would achieve the maximum number of contacts when completely surrounded by small shot. and further increase in the proportion of small shot would have no effect on the number of faces of the large shot. Under these conditions the number of faces on the small shot would come closer and closer

These results of experiments 1, 2, and 3 are shown graphically in figure 4, in which curve AA is based on the data for shot of uniform diameter (Marvin, 1939); BB represents the data of table 1 (experiment 1) on small shot, B'B' the data of table 1 (experiment 1) on large shot; CC and C'C' are curves for the data on the small and large shot, respectively, in table 2 (experiment 2), and DD and D'D' for the data on small and large shot, respectively, in table 3 (experiment 3). It is evident that curves BB, CC, and DD get progressively closer to AA, while curves B'B', C'C', and D'D' get progressively farther away from AA.

tively, are given. From table 4, for instance, it is evident that in experiment 1 the 50 small shot had a total of 22 triangular faces, 164 quadrilateral faces, 217 pentagonal faces, etc. Similarly in the 50 large shot there were 23 triangular faces, 179 quadrilateral faces, 380 pentagonal faces, etc. These faces were sometimes plane, sometimes more or less curved. Similarly, the edges were straight lines in some cases, in others not.

The results in tables 4, 5, and 6 are presented graphically in figure 5, in which BB is the curve for the data on the small shot in table 4 (experiment 1), B'B' the curve for the data on the large shot in table 4 (experiment1). Similarly CC and C'C' are

the curves for the data on the small and large shot, respectively, in table 5 (experiment 2), while DD and D'D' are the curves for the data on the small and large shot, respectively, in table 6 (experiment 3).

From these tables and curves it is evident that there were more pentagonal faces than any other kinds in the small shot in each of the three experiments. Of the total of 1742 faces on the 150 small shot, 760 were pentagonal. While the slope of the three curves, BB, CC, and DD is in general similar, both the number and proportion of hexagonal faces is least in experiment 1 (BB) and greatest in experiment 3 (DD).

An examination of the data and curves dealing with the large shot in each of these three experiments as given in tables 4, 5, and 6 and curves B'B'. C'C', and D'D' in figure 5 reveals that pentagonal faces were more common than any other kind in experiments 1 and 2, but that hexagonal faces were of greatest frequency in experiment 3 (D'D'). It is obvious that there were many more pentagonal than hexagonal faces in the large shot in experiment 1. and many more hexagonal than pentagonal faces in the large shot in experiment 3, while the large shot in experiment 2 were intermediate in this respect. The proportion of pentagonal to hexagonal faces changes very definitely in the large shot in these three experiments. The same is true to a less extent in the small shot.

Tetrahedral angles, in which four faces on a compressed shot meet in a point, were recorded in each of the three experiments. They were of occasional occurrence in the small shot and more frequent in the large shot. In the large shot they were least common in experiment 1, which had the fewest and consequently the largest faces, and most abundant in the large shot in experiment 3, which had the most numerous and consequently the smallest faces. In a liquid system tetrahedral angles are unstable (Kelvin, 1887). This can hardly be true in the same sense in the experiments under consideration here. In a system of solids, tetrahedral angles should be more and more common as the faces get smaller, since the likelihood of four faces meeting in a point becomes greater as the area of the individual faces becomes reduced. This was the case in the experiments just described. It was somewhat difficult to decide, in certain cases, whether a tetrahedral angle had actually occurred or not. All such angles were studied under a magnification of 50 diameters, and if they still appeared to have four faces meeting in a point, they were designated as tetrahedral. There were in all 39 tetrahedral angles and 9784 trihedral angles on the 300 shot examined, as well as 14,754 dihedral angles. The ratio of tetrahedral to trihedral angles was therefore 1:251. Relatively very few tetrahedral angles were present, in spite of the fact that surface tension can hardly be very significant in this system.

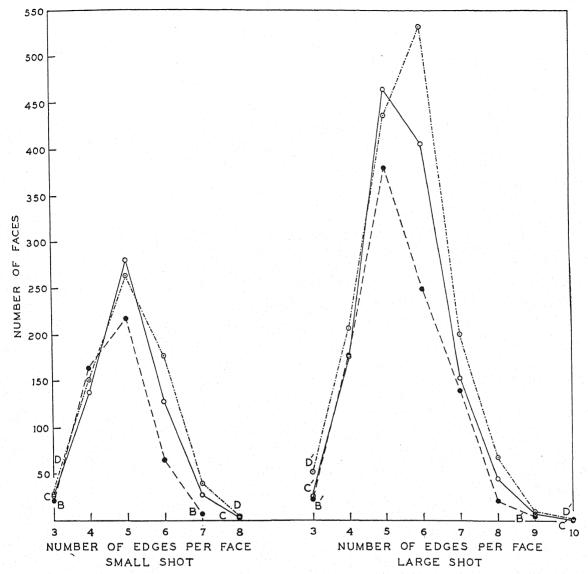

Fig. 5. Number of edges per face and the frequency of their occurrence (3-triangular, 4-quadrilateral, 5-pentagonal, etc.) in small and large shot. BB and B'B' are the curves for the small and large shot, respectively, in experiment 1; CC and C'C' the curves for the small and large shot, respectively, in experiment 2; DD and D'D' the curves for the small and large shot, respectively, in experiment 3.

It seems scarcely necessary to tabulate here the complete data on each of the 300 compressed lead balls studied, since the results have been presented in summary form above. Of the 300 shot carefully examined, one small one, in experiment 1, had only six faces, and these were all four-sided. Only one other shot, a small one in experiment 3, had faces all of one kind, twelve faces, all pentagonal. This was a pentagonal dodecahedron, showing some inequality in the faces and edges. None of the other 298 shot had the faces all alike. Of the 150 small shot 18 had only quadrilateral and pentagonal faces, in varying numbers, while one small shot in experiment 3 had 6 quadrilateral and 5 hexagonal faces, and another in experiment 1 had 6 quadrilateral

and 4 hexagonal faces. Many of the small and a few of the large shot had three kinds of faces, usually quadrilateral, pentagonal, and hexagonal, and many had more than three kinds of faces. None of the shot studied had twelve quadrilateral faces, as in the rhombic dodecahedron, nor were there any with eight hexagonal and six quadrilateral faces as in the orthic tetrakaidecahedron, though the two mentioned above did have only hexagonal and quadrilateral faces. The pentagonal dodecahedron was early discarded as a possible shape for cells in favor of the rhombic dodecahedron, since the former will not stack without interstices. The latter is also no longer accepted.

DISCUSSION AND CONCLUSIONS.—The data presented above indicate that in a system composed essentially of solids, in which surface tension is reduced to a minimum, the number of contacts is closely correlated with the proportion of small and large spheres. The work of Marvin (1937, 1939) shows that in solid spheres of uniform size, compressed to eliminate interstices, the number of contacts is 14 (14.17). Lewis (1923, 1925, 1933) found that cells in undifferentiated tissues have an average of almost exactly 14 faces (13.97 for 250 cells), so that there is a striking parallelism between the shot and the cells. It is to be expected, then, that there may well be correlations between large and small shot compressed together and large and small cells in tissues. The diameter ratios used in the shot, 1:2, may be expected of cells in tissues, and the ratios of the shot to the diameter of the cylinder are also in the same order of magnitude as the ratio of cell to pith diameters in the stems of certain plants.

When small and large shot are mixed together in the same cylinder and compressed, the number of faces on the small balls drops below 14, the number of faces on the large ones rises above 14. Using diameter ratios of 1:2, the average number of contacts of the small shot dropped to 9.5 when there was a large proportion, by volume, of the large shot; it rose to almost 14 (13.3) when a large proportion, by volume, of small shot was utilized. The greater the proportion of small shot, the closer the approximation was to 14. In the case of the large shot, a high proportion of this with reference to small shot caused an increase in the number of contacts from 14 to 19.98. As less and less of the large shot was mixed with the small, the number of faces on the large shot increased—to an average of 30.18 in experiment 3. Large shot surrounded by large shot have 14 faces on compression, but large shot partially or completely surrounded by small shot have more than fourteen. Under these varying conditions it is not possible to conceive of a polyhedron with a definite number of sides as an ideal type. The number of contacts in these experiments depends on the proportion of small and large shot; it is relatively fixed only for any one set of fixed conditions. In as far as similar factors hold for cells in tissues, the average number of contacts may be expected to vary with the proportion of small and large cells. If the cells are relatively uniform in size and intercellular spaces are insignificant, the number of faces expected is 14, as has been found to be the case (Lewis, 1923). If diameter ratios of the cells vary, the smaller cells would be expected to have fewer than 14 faces, the larger cells more than 14.

In the experiments described above, the diameter ratio of 1:2 was kept constant. Changing this ratio would also have an effect on the number of contacts. If a ratio of 1:4 were used, for instance, a still greater number of faces would be expected on the large shot. Under varying conditions of diameters

and number or volume of shot no one ideal type with a fixed number of faces holding for all experiments would be expected. It did not occur in the work described.

As the number of contacts changes with the varying proportions of small and large shot, so the proportion of pentagonal and hexagonal faces also varies under these changing conditions. This is especially evident from the large shot in experiments 1, 2, and 3. In the large shot in experiment 1 pentagonal faces were by far the most common, in experiment 3 there was a marked preponderance of hexagonal faces. An ideal type of contact or a fixed proportion of quadrilateral, pentagonal, hexagonal. etc., faces, rigid under the varying conditions in these experiments, is therefore also inconceivable. The number of contacts changes with the varying proportions of large and small shot, and the relative abundance of the kinds of contacts, whether triangular, quadrilateral, etc., similarly changes.

In experiment 1, in which there were numerically approximately 2 small shot to 1 large, the average number of faces, considering small and large shot together, was 13.0. In experiment 2, in which about 8 times as many of the small as of the large shot were used, the average of all the central shot rose to 13.6; in experiment 3, with 32 small to 1 large shot, the average was 13.8. Professor Lewis has kindly suggested that "it has previously been shown that in an aggregation of 14-hedral cells, if divisions occur in hexagonal planes (avoiding the unstable tetrahedral angles or edges where four cells meet), the average of the 14 facets will be maintained. It will rise if the division planes have more than 6 sides; it will fall if these planes are pentagonal, quadrilateral, or triangular. Thus averages of 13 sides per cell, as found in these shot, might be produced in organic tissue by division, as well as by

adjustment in proportion to size."

It is true that lead shot and cells in tissues differ greatly in many respects. Presumably the apical meristems in stems and roots as well as the regions of differentiation contain cells with liquid or semiliquid contents in which surface tension phenomena, colloidal properties, and biological factors are operative, none of which play any important part in lead shot. On the other hand, contact and pressure are of significance also in determining the shape of cells, as they are in the lead shot—more so, undoubtedly, in certain regions and tissues of the plant than in others. Although there are differences, this similarity is an important one, especially in view of the close correlation established by Lewis and Marvin between cell shapes and compressed shot of uniform diameters. The movement of the shot in one direction in the cylinder may be looked upon as one of the shortcomings of the experiments and is in no way correlated with the much-discussed question of slipping and gliding growth.

The data presented above throw light on one set of factors, contact and pressure, in cell shape determination. The mechanics of the process cannot be fully understood until the other factors have also been studied. The results here given will take on added significance when cells of varying sizes in the same tissue have been modeled and their three-dimensional shape has been determined. The evidence from the lead shot indicates that such cells will vary in the number of contacts, and consequently in shape, depending, partly at least, on the relative sizes and numbers of large and small cells; it shows also that the abundance of triangular, quadrilateral, hexagonal, etc., faces will be affected by the proportion of the cells of each size that occur in the tissue.

#### SUMMARY

Previous work of Lewis shows that cells in undifferentiated tissues have an average of 14 faces, while that of Marvin proves that in lead shot of uniform diameters compressed so that there are no interstices, there are also approximately 14 contacts

Since cells in tissues vary in size, lead shot of two diameters, with a ratio of 1:2, i.e., with volumes of

1:8, were mixed in varying proportions and compressed to eliminate all spaces.

Under these conditions the average number of faces on the small shot was always less than 14, varying from 9.5 to 13.3, while the average number of contacts on the large shot was always greater than 14, ranging from 19.98 to 30.18.

The average number of faces of all the central shot, large and small, considered together, varied from 13.0 to 13.8, giving fairly close approximations to the results obtained by Lewis in cells.

The proportion of hexagonal and pentagonal faces, especially on the large shot, varied, depending upon the conditions of the experiments.

In as far as contact and pressure determine cell shapes, it is to be expected that the association of small and large cells in the same undifferentiated tissue will result in fewer than 14 faces on the smaller cells and in more than 14 contacts on the larger ones.

# THE USE OF INDICATOR PLANTS IN LOCATING SELENIFEROUS AREAS IN WESTERN UNITED STATES. II. CORRELATION STUDIES BY STATES 1

O. A. Beath, C. S. Gilbert, and H. F. Eppson

The basic purpose of our correlation of seleniferous plants vs. rocks has been to determine to what extent certain native plants can be depended upon to indicate a seleniferous soil where environmental factors are known to be different from those in Wyoming. In those states in the Rocky Mountain region having geological formations stratigraphically equivalent in age (e.g., Cretaceous and Tertiary) to those of Wyoming, it was expected that a certain degree of similarity would prevail as to the selenium content of the rocks and the indicator plants rooted in them.

Byers (6) (1935 report) stated, "It was hoped that certain plants might serve as indicators either by their presence or absence or that contours or other soil conformities might aid. No indications based upon plant distribution were detected by Mr. Piemeisel nor did any topographical indications seem useful." In 1936 the authors undertook to study the character of seleniferous indicator plants outside of Wyoming. The data in this paper include selenium analyses of indicator plants and a certain amount of miscellaneous vegetation from Arizona, California, Colorado, Idaho, Montana, Nevada, New Mexico, North Dakota, Oregon, South Dakota, Texas, and Utah. Seleniferous indicator plants from these states are correlative with geological formations comparable in age to those previously described by the authors, and in addition to those we have introduced several formations believed to be new assignments.

Data on the seleniferous vegetation of Wyoming have been rather fully discussed in earlier reports (1, 2, 3, 5, 12). The tabulation of rock and soil analyses (selenium) have been purposely omitted from this treatise. Unless samples of this character are taken so as to be representative of the seleniferous areas in which a plant's roots are imbedded, misleading results may be obtained. Furthermore the total amount of naturally occurring selenium is no index as to its availability (3, 12), nor is it always certain to indicate the probable seleniferous status of a natural selenium-absorbing plant.

Confirmatory evidence shows that a native indicator plant can become extremely seleniferous on a soil carrying moderate concentrations. On the other hand, the same plant species may be only moderately seleniferous on a soil carrying high concentrations of selenium. Analytical data involving the selenium content of rocks and soils are important in interpreting the broad aspects of the selenium problem.

Vegetation influenced by its selenium content is primarily a range problem. This is due to the fact that the natural habitat of the main absorbing plant

<sup>1</sup> Received for publication February 6, 1939.

species remains quite undisturbed. Consequently the authors have confined their investigations largely to those phases that apply to the grazing sections. We have not been concerned with isolated occurrences of selenium in ore bodies or specially enriched zones incapable of supporting a significant areal seleniferous plant cover.

Marine sediment relationships.—Geological formations stratigraphically equivalent in age vary in character and in thickness from one area to another in Wyoming. Likewise similar variations occur in the stratigraphy of the Rocky Mountain region.

Marine sedimentary rocks which were deposited contemporaneously are subject to striking lateral changes in their lithology, or physical constitution. Sandstones deposited adjacent to ancient shores grade into mudstones which were deposited farther from shore. These, in turn, grade into limestones deposited far from shore over areas in which the deposition of land-derived fragmental material was at a minimum. It is thus apparent that different kinds of sediments are deposited over adjacent areas at the same time, and the deposits are therefore said to be of the same age. Each of these rock types, of the same age but of different lithology, is referred to as a facies.

Contemporaniety of facies is determined through the use of fossils. It is believed that a species appeared, flourished for a certain length of time, then became extinct. Consequently, when specimens of species whose time-span is known to have been brief are found in different localities, the beds in which they are found, irrespective of lithology, are thought to have been deposited during the same geologic time.

Good examples of lateral variation and gradation (fig. 15) are found in the Cretaceous rocks of the Great Plains and the Rocky Mountains. Fossils

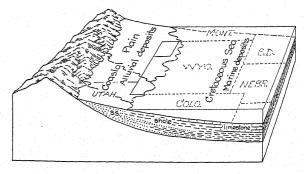

Fig. 15. Diagram of the central portion of the Rocky Mountain Region showing the contemporaneous deposition of marine and non-marine sediments during early-Upper Cretaceous time.

which characterize Niobrara time (the time during which the Niobrara formation was deposited) are found in the Fort Hays limestone and the Smoky Hill chalk of central Kansas (19), in the Niobrara calcareous shale in the Rawlins uplift of south central Wyoming (8), and in the sandstones of the upper Frontier formation of southwestern Wyoming (20). It is believed, therefore, that the limestone, shale, and sandstone represent contemporaneous deposition at different distances from the land mass to the west of Wyoming which bordered the Cretaceous sea. With such a manifest change in sediments in the Niobrara formation over areal distribution of several hundred miles, it is not surprising to find variations in the selenium content of the rocks of this type. In general the Hilliard and Cody shales of western Wyoming are much leaner in selenium than the calcareous shales of central Wyoming. This relationship is borne out by a comparison of the seleniferous condition of the same plant species from these

A similar gradation in lithology is shown by somewhat older Cretaceous rocks across the same area. A widespread fauna, characterized by certain fossil cephalopods, occurs throughout a large area in the Great Plains and Rocky Mountains. These fossils are found in the Codell sandstone member of the Carlile shale in Kansas and eastern Colorado, and in the Wall Creek sandstone member of the Frontier formation in south central Wyoming. In central Kansas, the Codell lies about 200 feet stratigraphically above the top of the Fairport chalky member of the Carlile, about 85 feet thick, which rests on the Greenhorn limestone, about 100 feet thick. Therefore, some 300 feet of calcareous beds lie 200 feet below the Codell sandstone. In south central Wyoming the Wall Creek sandstone rests on a noncalcareous shale sequence nearly 1000 feet thick. Consequently, at the time that calcareous sediments were being deposited in Kansas, muds were being deposited in south central Wyoming. In addition, some of the coal-bearing continental standstones in the lower Frontier of southwestern Wyoming were deposited at essentially the same time.

The illustrations just cited show in principle what may be expected to apply rather generally to all the sediments deposited during Cretaceous time. Formations of continental origin, of course, are made up largely of the source rocks from which the sediments were derived.

The subject matter and experimental data that follow are presented separately for each state. The investigation of seleniferous indicator plants and their geological relationships involving several western states was initiated in 1936. Consequently the data include material obtained over a period of three years. Collecting samples from all these areas and the inclusion of pertinent range data were possible only through the cooperation of several agencies. In this we were aided by representatives of the U. S. D. A. Soil Conservation Service, U. S. Forest

Service, U. S. Biological Survey, botanists, geologists, archaelogists, chemists, and others.

It is our hope that the data given will be interpreted within the limitations previously discussed in this report.

In presenting the results of analysis of plants from various states, the following information is listed for each sample: name; laboratory sample number; part of plant analyzed; stage of growth when plant was collected; location; geological data consisting of (1) type of rock on which the plant was growing, (2) geological formation or group to which the rock type belongs, and (3) the geological age to which the formation or group is assigned; and finally, the selenium content of the plant expressed in parts per million (p.p.m.). In some instances not sufficient geological data are as yet known to us to give all the desired information, in which case a dash indicates the incompleteness of the geology.

The selenium content of the plants is reported on a bone dry (b.d.), air dry (a.d.), or partly dry (p.d.) basis. Where the result is given as negative (neg.), there was either no selenium found by analysis or the amount present was less than 1 p.p.m. on a bone dry basis, an amount deemed insignificant from an economic viewpoint.

# ARIZONA

The principal indicator plants occupying seleniferous areas in Arizona are species of Stanleya and Astragalus. It will be observed that a large number of species of Astragalus were collected and analyzed for selenium. These analyses were made to determine which species of Astragalus are indicators of a seleniferous soil. It is apparent from these analyses that indicator plants are restricted to limited areas. This point is clearly illustrated by the comparatively wide distribution of the non-selenium-bearing Astragalus diphysus, A. wootoni, A. calycosus, and the restricted distribution of the selenium-absorbing Astragalus praelongus or A. confertiflorus.

There are several areas in Arizona where Stanleya pinnata, Astragalus praelongus, and A. preussii are reported to occur that have not been investigated. The data given in this report include analyses of vegetation associated with representative rock types from a number of places. The most seleniferous plants were found to occur in northeastern Arizona. This conclusion is based upon the evidence supplied by analyses of Astragalus praelongus, indigenous to the Winslow-Holbrook section. Rocks in this area that are correlative with seleniferous plants are Triassic (basal) in age and are equivalent stratigraphically to the basal Chugwater (5) formation (Triassic) of Wyoming and Colorado.

In the Kaibab Reservation the seleniferous Astragalus confertifiorus was collected on what is believed to be the Moenkopi formation. The Moenkopi is Triassic (basal) in age. Reference has been made to this formation in connection with certain selenif-

erous vegetation in southern Utah. Consequently its seleniferous character seems to be definitely established in the areas studied.

Stanleya pinnata occurs in the Tonto basin of central Arizona. It grows in scattered patches from the Payson area to the Roosevelt Reservoir. Composite samples, at the early flower stage of growth, were selected from several areas in the valley. Selenium was present in all the samples. The sediments in which the Stanleyas were rooted are believed to be Pliocene (Tertiary) (22) in age. Reference has been made to the probable origin of analogous seleniferous rocks elsewhere—e.g., the Payette formation of southwestern Idaho—placing emphasis upon the fact that the older rocks from which these seleniferous sediments were derived is particularly significant.

The seleniferous Astragalus sabulosus has been observed to occur in the Upper Verde Valley of north central Arizona. In this locality the valley floor sediments (Verde formation), in which the A. sabulosus grows, are Tertiary or Quaternary (9) in

A sample of Stanleya pinnata from the Soil Conservation Service nursery near Tucson was seleniferous. The specimens were growing in a soil derived from rocks of a local character commonly referred to as caliche.

Stanleya pinnata was observed to occur along the Bright Angel Trail in the Grand Canyon. It was not found to occur until the Trail intercepted the Supai formation a considerable distance below the south rim of the canyon. The Supai is of Permian and Pennsylvanian age.

Aster abatus (Xylorrhiza tortifolius) is reported to occur in a number of areas in western Arizona. Type specimens from Utah and California were not seleniferous. It is believed that Aster abatus is not dependable as an indicator of a seleniferous soil.

#### CALIFORNIA

The preliminary survey of the seleniferous plants in California was confined to the southern part, principally in Riverside, Imperial, and San Bernardino counties. Only those areas were selected that carried species of Stanleya, Astragalus limatus Sheld., and Aster abatus Greene (Xylorrhiza tortifolius Gray). In so far as our investigations have gone, it is apparent that the seleniferous Stanleya pinnata is associated with two geological formations, one the White Tank Monzonite and the other a poorly defined calcareous type of rock designated as caliche. The latter is much more common than the White Tank Monzonite in the areas studied. The only formation in the Twenty-nine Palms area capable of supporting Stanleya is the White Tank Monzonite. This formation is intruded into pre-Cambrian rocks and is believed to be of Jurassic age (15). Careful search failed to reveal Stanleya growing on any of the pre-Cambrian rocks exposed in this area. Areas in the Mohave Desert capable of supporting Stanleya pinnata appear to be confined to a rock type of a calcareous nature.

Aster abatus was found to occur on various rock types. In no sense is this species an indicator of a

seleniferous soil.

Astragalus limatus occurs abundantly in Imperial County near Truckhaven. It was selected for its selenium-absorbing properties because it belongs to the Preussii group. A. limatus was distinctly seleniferous in the areas investigated. It was found to

grow in sediments of Quaternary age.

The Stanleya elata occurs in areas in Death Valley. It is reported to be rather numerous in certain localities from 4000 to 5000 feet elevations. Mr. M. French Gilman, Death Valley National Monument, states that S. elata "grows on flats and canyons at these altitudes but does not seem to be very widely distributed over the valley at the proper altitudes." Mr. Gilman has also observed it growing in the Panamint and Grapevine Mountains. As a food, Mr. Gilman states, "The Indians use the young leaves as greens but tell me they have to throw out the first water when it boils and finish the cooking in fresh water, otherwise the greens make them sick if they do not cook it that way." Stanleya elata from the Death Valley has not been analyzed for selenium.

The selenium content of the Stanleyas included in our preliminary correlation studies is in general very low. There are two points to be considered in this connection. If selenium is essential to the normal development of the Stanleya species, how much of it is necessary? The other consideration has to do with the amount of selenium that would be necessary to cause a Stanleya to be toxic to physiological processes. The first query cannot be answered. The presumption might be that under extremely arid conditions a part or two per million of selenium in the plant is all that is necessary for the Stanleyas to develop normally. To be toxic a considerably larger concentration would be necessary. Just what

this would be cannot be given at this time. Our data are not complete for the seasonal variations of the selenium content in the Stanleyas investigated. In the Rocky Mountain region the Stanleyas start their growth directly from the roots. Stanleya pinnata in southern California sends out new leaves from the old stems. In the former, one would be concerned with a new development, while in the latter, the sampling would include partially dried out stems as well as green leaves. This disparity might make a considerable difference in the final analytical results.

The Stanleya collections, it will be observed, represent but one sampling. Some analyses were made from herbarium specimens and results reported merely as positive. While purely qualitative, it was concluded that an exact determination would in no way be representative of fresh material, hence the test was carried only to the point where selenium was definitely indicated.

A few soil and rock samples were collected and analyzed for selenium. Most of the material of this character was taken from the surface, consequently the results could not be considered representative of the seleniferous rocks where the *Stanleyas* were taken. These results and others will be held in abeyance until additional field evidence has been obtained.

The restricted growth of Stanleya pinnata in the areas studied indicates that it is extremely selective in its growth. Until evidence to the contrary is produced, its occurrence may be regarded as indicative of a seleniferous soil, at least sufficient so to supply the plant's requirement.

# COLORADO

In 1936 the authors cooperated with the United States Soil Conservation Service in Colorado in the study of the distribution of seleniferous indicator plants. The areas included in these exploratory surveys were located in east-central Colorado. The native plants selected for study were Astragalus bisulcatus, A. racemosus, A. pectinatus, species of Oonopsis, Stanleya, and Xylorrhiza. The initial collections were confined to those sections where many of these indicator plants were reported to occur. Geological correlations were made after the chemical analyses had been completed. This special use of indicator plants is an excellent illustration of their value to range botanists in locating seleniferous soils particularly where the soil cover is not easily referable to a geological background. Reference to the chemical analyses in this report indicates the general consistency of the seleniferous character of the indicators collected by staff members of the Soil Conservation Service. Plants obtained by the survey are identified by the prefix-Colo. 1, 2 -Allred A, B, etc. The analyses also include mis-

\* White Tank Monzonite.

cellaneous samples of vegetation common to the areas explored. These analyses were made for comparative purposes. In the selection of grass samples it was the usual practice to obtain them from soils where the seleniferous indicator plants had had an opportunity to exert a favorable influence in the development of available selenium.

Preliminary studies of selenium occurrences in native plants in the Durango section were undertaken in 1937. These investigations were executed cooperatively with the wildlife division of the United State Forest Service. The important indicator plants were found to be Astragalus pattersonii, A. haydenianus, A. urceolatus, and A. confertiflorus. Astragalus pattersonii occurs widely distributed in the Durango area. It is restricted, as are all the other seleniferous Astragali, to definite geological formations. Mr. L. E. Coughlin, Wildlife specialist, also collected a number of the common forage plants and shrubs for selenium analysis. Its general absence from such vegetation is in agreement with results obtained elsewhere. Interpreted broadly, these results confirm the authors' conclusions that most forages and shrubs are incapable of absorbing selenium in toxic quantities from raw seleniferous shales.

In western Colorado our explorations brought us in contact with a number of seleniferous indicator plants. Collections were made usually from areas adjacent to the highways traversed. Consequently the extent to which the indicator plants are distributed geographically in this part of Colorado is not known to us. The indicator plants encountered were Astragalus confertiflorus, A. haydenianus, A. pattersonii, species of Xylorrhiza, and Stanleya. In the Craig-Meeker-Rifle area dense stands of Astragalus haydenianus and A. pattersonii were observed. These plants occupied pastures, roadside banks, and the borders of irrigated fields. Scattered patches of Stanleyas occurred in the same general areas.

In the Grand Junction-Fruita area are extensive growths of Stanleya, Xylorrhiza, and Astragalus. With the exception of the Xylorrhiza specimens, all the plants collected were green and vigorous. The stage of growth in which Xylorrhizas reach their maximum selenium intake has been considered (4).

The geological formations of Colorado, included in this report, that support seleniferous plants involve rocks of Jurassic, Cretaceous, and Tertiary age.

Morrison.—The Morrison formation is upper Jurassic (21) in age. Indicator plants growing on rocks of the Morrison in Colorado were seleniferous in the areas investigated. In its type section at Morrison, Colorado, the Morrison formation is 325 feet thick. Throughout Wyoming the Morrison formation ranges in thickness from 150 feet to 250 feet. The causes in thinning of this formation may be (1) deposition on an irregular erosional surface or (2) portions may have been removed by pre-Cloverly erosion. It is not known whether or not

the upper portion of the Morrison formation in its type locality is seleniferous. Scattered exposures of the Morrison in western Colorado have not been in-

vestigated by us for indicator plants.

Dakota Group.—Throughout much of Colorado and Wyoming there is a succession of standstones, shale, and conglomerates, for the most part of fresh water origin, which lie between the Morrison formation and the Benton shale. This succession has been referred to as the Dakota Group. It is believed to be of upper Cretaceous age. The basal portion may be older.

Cloverly formation.—In the Glendevey area of northern Colorado the basal conglomerate member of the Dakota group is referred to as the lower

member of the Cloverly formation.

Benton shale.—The Benton shale is upper Cretaceous in age. In parts of Wyoming and eastern Colorado the rocks (21) formerly called Benton are now divided into (descending) Carlile shale, Greenhorn limestone, and Granerous shale. In southcentral Wyoming and the Bighorn Mountains they are divided into (descending) Carlile shale, Frontier formation, Mowry shale, and Thermopolis shale.

Mancos shale.—The marine Mancos shale has yielded faunas (18) (in ascending order) of Greenhorn, Carlile, Niobrara, and Pierre age. It is upper

Cretaceous in age.

Niobrara formation.—The Niobrara is upper Cretaceous in age. It is the upper member of the Colorado group. The generally accepted (21) definition of the Colorado group includes only Benton and Niobrara and their equivalents.

Pierre formation.—The Pierre is upper Cretaceous in age. It is the lower formation of the Mon-

tana group.

Lewis formation.—The Lewis formation is upper Cretaceous in age. In a general way it is synchronous (17) with some part of the middle and upper portions of Pierre shale to the east of Rocky Mountains but more exact correlations cannot be made until further field evidence is available. The Lewis shale of southern Wyoming and northern Colorado is not (17) the same as the Lewis shale of San Juan Basin of southern Colorado. The Lewis shales of the San Juan Basin have not been explored for indicator plants.

Lance formation.—The age of Lance formation is in question. In northwestern Colorado it is prob-

ably upper Cretaceous in age.

Animas formation.—The Animas is probably Ter-

tiary (Eocene?) in age.

McDermott formation.—The McDermott forma-

tion is upper Cretaceous in age.

Wasatch Group (Wasatch formation).—The name Wasatch has been widely applied both as a group and as a formation to successions of rocks which are believed to have been deposited in Paleocene and lower Eocene through the Rocky Mountain region. These successions were deposited in the intermontane basins and the rock débris of which they are composed was derived from adjacent mountains;

consequently the succession varies widely from basin to basin. Locally (12) these rocks support seleniferous vegetation. In central and southern Wyoming the seleniferous indicator plants growing on these rocks are as seleniferous as those growing on rocks of Cretaceous age.

Triglochin maritima L., Colo. 24; tops; seed; South Park; Shale, Pierre Fm., Cretaceous; 12 p.p.m., b.d.

Triticum species, D567; grain; seed; near Durango; Shale, Mancos Fm., Cretaceous; 2 p.p.m., a.d.

Xylorrhiza glabriuscula Nutt., T5; tops; past seed; 7 mi. N.W. Fruita; Shale, Mancos Fm., Cretaceous; 4 p.p.m., a.d.

Zinnia species, Colo. 50; tops; bloom; 10 mi. W. Trinchera Creek near Trinchera; Shale, Niobrara Fm., Cretaceous; 9 p.p.m., b.d.

#### IDAHO

Two areas in Idaho have been examined critically by us for the distribution and kind of selenif-

erous vegetation. These areas were selected because of the occurrence on them of species of Stanleyas. In the Glenns Ferry section, seleniferous soil is confined exclusively to the Payette formation of Miocene age (Tertiary). The significant point to be kept in mind in the study of all seleniferous sedimentary formations of Tertiary age is that the source rock, of older age, from which the sediments were derived must have been seleniferous. Analyses of indicator plants from the Payette formation indicate that the selenium is distributed rather uniformly throughout the formation. The formations immediately below and above it are incapable of supporting seleniferous vegetation. The principal indicator plants on the Payette formation are Stanleya pinnata, S. bipinnata, and Astragalus toanus.

The second area near Winsper, Lemhi County, attracted our attention because of the abundance there of Stanleya viridiflora, Astragalus bisulcatus, and Aster adscendens. Reference to the data on these species shows a marked seleniferous condition particularly from the zone where the rocks are classified as massive limestones. Overlying the Paleozoic rocks are travertine deposits of Tertiary age. Indicator plants on the travertine deposits were much leaner in selenium than those growing on the limestones for the same stages of growth.

The influence of highly seleniferous plants upon associated vegetation is clearly demonstrated in this area. Attention is directed to the selenium values of many plant species not ordinarily capable of absorbing selenium unless made available to them. The principal contaminator plants in this area are Aster adscendens and Astragalus bisulcatus. The same plant species away from this immediate influence were usually non-seleniferous.

Soil samples from a cut bank below the limestone outcrop gave the 1st foot 1.13, 2nd foot 1.03, and the 3rd foot 0.79 parts per million selenium, respectively.

# Idaho Plant Samples

- Agropyron spicatum (Pursh) Scribn. and Smith, E462; tops; flower; 6 mi. S.E. of Twin Buttes; Igneous, ——, Quaternary?; Neg.
- Amsinckia intermedia Gray, E194; tops; flower; King Hill; Lake sediments, Payette Fm., Miocene; Neg.
- Artemisia spinescens D. C. Eaton, E209; tops; flower; 4 mi. S. of Castle Rock; Lava flow, —, Tertiary; Neg. Aster species, E188; tops; flower; Hagerman Draw; Lake sediments, Payette Fm., Miocene; Neg.
- A. species, E198; tops; flower; W. of Soda Springs; Igneous, Tertiary, Neg
- neous, —, Tertiary; Neg.

  Astragalus species, E215; tops; flower; Declo; Igneous,
- A. species (Probably new species, related to A. artemisiarum Jones and A. amplexus Payson), E211; tops; flower; 2 mi. W. of Mountain Home; Lake sediments, Payette Fm., Miocene; Neg.
- A. species (Same as above, probably new species), E212; tops; flower; King Hill; Lake sediments, Payette Fm., Miocene; Neg.
- Astragalus aculeatus A. Nels., E195; tops; flower; N.W. of Grand View; Lake sediments, Payette Fm., Miocene; Neg.

- A. amphioxys Gray, E191; tops; flower; Indian Cove; Lake sediments, Payette Fm., Miocene; Neg.
- A. curvicarpus (Sheld.) Macbr., E218; tops; flower; 2 mi. N.W. of Grand View; Lake sediments, Payette Fm., Miocene; Neg.
- A. diphysus Gray, T15; tops; past seeding; 67 mi. E. of Twin Falls; Alluvium, ——, Quaternary; Neg.
- A. lentiginosus Dougl. or A. heliophilus (Rydb.) Tides.,
   E187; tops; flower; 10 mi. E. of American Falls; Igneous, —, Tertiary; Neg.
- A. lonchocarpus Torr., E185; tops; flower; Bliss; Lake sediments, Payette Fm., Miocene; Neg.
- A. toanus Jones, E183; tops; flower; 3 mi. W. of Hammett; Lake sediments, Payette Fm., Miocene; 280 p.p.m., b.d.
- A. toanus Jones, E184; tops; flower; Bliss; Lake sediments, Payette Fm., Miocene; 622 p.p.m., b.d.
- A. utahensis T. & G., E204; tops; flower; 10 mi. W. of Wyoming line; Limestone, Thaynes Fm., Triassic; Neg.
- Atriplex species, E190; tops; seed; Hagerman Draw; Lake sediments, Payette Fm., Miocene; 4 p.p.m., b.d.
- Atriplex nuttallii S. Wats., E206; tops; flower; Orchard; Lava rock, —, Tertiary; Neg.
- Crepis acuminata Nutt., E217; tops; flower; 3 mi. W. of Hammett; Lake sediments, Payette Fm., Miocene; 2 p.p.m., a.d.
- Elymus condensatus Presl., E490; tops; flower; 10 mi. N.E. of Twin Buttes; Igneous, —, Quaternary?; Neg.
- Eurotia lanata (Pursh) Moq., E214; tops; flower; Bliss; Lake sediments, Payette Fm., Miocene; 5 p.p.m., a.d.
- Grayia spinosa (Hook.) Moq., E199; tops; flower; Bliss; Lake sediments, Payette, Miocene; 6 p.p.m., a.d.
- G. spinosa (Hook.) Moq., E220; tops; flower; 4 mi. S. of Castle Rock; Lava rock, —, Tertiary; Neg.
- Lithospermum species, E197; tops; flower; Bliss; Lake sediments, Payette Fm., Miocene; Neg.
- Mentzelia dispersa S. Wats., E189; tops; flower; Walters; Lake sediments, Payette Fm., Miocene; Neg.
- Oryzopsis species, E205; tops; flower; 2 mi. N.W. of Grand View; Lake sediments, Payette Fm., Miocene;
- Oryzopsis hymenoides (R. & S.) Ricker, E492; tops; flower; 10 mi. N.E. of Twin Buttes; Igneous, —, Quaternary?; Neg.
- Sitanion hystrix (Nutt.) J. G. Smith, E491; tops; flower; 10 mi. N.E. of Twin Buttes; Igneous, —, Quaternary?; Neg.
- Stanleya bipinnata Greene, E201; tops; flower; Bliss; Lake sediments, Payette Fm., Miocene; 364 p.p.m., b.d.
- S. bipinnata Greene, E207; tops; flower; King Hill; Lake sediments, Payette Fm., Miocene; 304 p.p.m., b.d.
- S. bipinnata Greene, T14; tops; seed; King Hill; Lake sediments, Payette Fm., Miocene, 352 p.p.m., a.d.
- S. pinnata (Pursh) Britt., E186; tops; flower; 11 mi. S.W. of Hammett; Lake sediments, Payette Fm., Miocene; 419 p.p.m., b.d.
- S. pinnata (Pursh) Britt., E196; tops; flower; N.W. of Grand View; Lake sediments, Payette Fm., Miocene; 53 p.p.m., b.d.
- S. pinnata (Pursh) Britt., E216; tops; flower; 3 mi. W. of Hammett; Lake sediments, Payette Fm., Miocene; 787 p.p.m., b.d.
- S. viridifiora Nutt., E301; tops; flower; Pocatello; Alluvium, —, Pleistocene; 2 p.p.m., b.d.
- S. viridifiora Nutt., E461; tops; flower; 6 mi. S.E. of Twin Buttes; Igneous, —, Quaternary?; 2 p.p.m., b.d.

- S. viridiflora Nutt., E489; tops; flower; 10 mi. N.E. of Twin Buttes; Igneous, ——, Quaternary?; 2 p.p.m., b.d.
- Tetradymia glabrata Gray, E193; tops; flower; near Bruneau; Lake sediments, Payette Fm., Miocene; Neg.
- T. glabrata Gray, E210; tops; flower; 3 mi. W. of Hammett; Lake sediments, Payette Fm., Miocene; Neg. T. spinosa H. & A., E213; tops; flower; Grand View;
- Lake sediments, Payette Fm., Miocene; 4 p.p.m., a.d.

  Thelypodium laciniatum var. milleftorum (A. Nels.) Pay-
- Townsendia florifer (Hook.) Gray, E208; tops; flower; King Hill; Lake sediments, Payette Fm., Miocene; Neg.

Water Cress, E800; tops; flower; Warm Springs Creek; Travertine, —, Tertiary; 16 p.p.m., b.d.

# MONTANA

Exploratory surveys of indicator plants in Montana have been confined to two species, principally Astragalus bisulcatus and A. pectinatus. The main collections were made along highways from a point near Browning and continuing generally eastward to Shelby, Great Falls, Havre, Malta, Wolf Point, Circle, and Glendive. Twenty-seven samples of A. pectinatus and fifteen of A. bisulcatus were taken along this route. The stage of growth of the A. bisulcatus plants was largely past flower or early seed stage. Since A. pectinatus matures earlier than A. bisulcatus, our collections of it (July) included plants in the past seeding stages. Several samples

contained no fruiting heads. All of these Astragali were seleniferous.

The second area to be investigated was in the southeastern part of the state. Collections were made in the late fall; hence, the selenium results derived from these samples must be interpreted with this seasonal influence in mind.

Several geological formations capable of supporting seleniferous plants outcrop in Montana. In the areas investigated the principal formations belong to the Colorado group—namely, the Judith River, Claggett, Bearpaw, Lance, and Fort Union.

Colorado Group.—Upper Cretaceous in age. The generally accepted definition (21) of the Colorado Group includes only Benton and Niobrara and their equivalents. It was named for exposures at east base of the Rocky Mountain Front Range in Colorado.

Bearpaw, Claggett, and Judith River.—These formations are upper Cretaceous in age and in general are equivalent to the Steele, Mesaverde, and Lewis formations of south central Wyoming.

Lance.—The age of the Lance formation is in question. In eastern Montana it is believed to be upper Cretaceous.

Fort Union.—The Fort Union formation is of Eocene age (Paleocene or basal Eocene of some writers) and overlies the Lance.

The occurrence of seleniferous plants in these various geological formations in Montana is correlative with the seleniferous character of rocks deposited contemporaneously in Wyoming and other states. The selenium content of Astragalus pectinatus growing on the rocks and soils of the Fort Union formation establishes the continuity of its seleniferous character. This statement is substantiated by earlier work.

# Montana Plant Samples

- Aster species, D582; tops; past seed; 1 mi. N.E. of Fort Benton; Shale, Colorado Grp., Cretaceous; 10 p.p.m.,

#### NEVADA

The authors became interested in the study of seleniferous indicator plants in Nevada because of the wide occurrence of the Stanleyas. In the late summer of 1937 collections of Stanleyas were made near the following towns: Wells, Battle Mountain, Fernley, and Winnemucca. Occurrences were noted at many other points along the highway particulary from Carson's Sink to Reno. The specimens collected were from old, badly weathered plants. Specific identifications were impossible in most instances for this reason. In 1938 (June) additional collections were made from other areas in Nevada. These collections were made near the following towns: Hawthorne, Crystal, Las Vegas, Ely, Caliente, Tonopah, Current, Mina, Hudson, Ludwig, and Lovelock.

The 1937 (D-samples) Stanleya collections were found by chemical analysis to be rather generally low in selenium. Because of the poor quality of specimens available to us, these low results should be interpreted with this point in mind. Surface soil samples were taken from some areas where the weathered Stanleyas grew. A few of these soil

analyses are given to illustrate the confusion that may develop in the interpretation of what constitutes a seleniferous area. Stanleya collections D-530, 531, 532, 533 and 534 gave only traces of selenium. Corresponding soil samples (surface 1 foot in depth) gave 1.22, 2.20, 1.20, none, and 1.25 parts per million selenium, respectively. It was also determined that in some Stanleya areas surface soil samples were negative for selenium, whereas the plants rooted in them (deeper soils) were seleniferous. These confusing results serve to illustrate the importance of soil sampling to the depth in which the plants are rooted.

It is realized that our brief exploratory investigations of the seleniferous status of indicator plants in Nevada are inadequate to evaluate even the areas referred to in this report. A few generalizations can be pointed out, however, as a result of our studies. One is that the Stanleyas as a whole are comparatively low in selenium. Whether this is due to a low soil selenium content or to environmental influences is not known to us. Indicator plants collected in the vicinity of the Toano Mountain Range in Elko County and the Shell Creek Range in White Pine County gave comparatively high selenium values. The seleniferous Astragali included: A. haydenianus, A. preussii, and A. toanus.

A complex series of rocks occur in Nevada. In a number of instances the geological formations are not known to us. Rocks of Cretaceous age or their equivalents are not represented in the areas dis-

cussed in this report.

In southeastern Nevada Astragalus preussii and Stanleya pinnata arcuata were collected from the detritus of massive limestones. These rocks are believed to be of Pennsylvanian age. In northern Nevada a sample of seleniferous Stanleya pinnata was taken from rocks assigned to the Humboldt formation of Tertiary age (Pliocene). This formation (11, 21) extends in patches from the west base of the Wasatch Mountains in Utah to the Humboldt River and Mountains in Nevada. Louderback (13) believes the Humboldt (Pliocene) and Lake Lohontan (Quaternary) lake beds are identical. Igneous rocks and sediments of Tertiary and of Quaternary age occupy many of the areas where Stanleya samples were taken. The source rocks from which the sediments were derived naturally would be older. however, the time (geological) of deposition determines the age of the formations.

It is believed that our correlation studies in Nevada support the general principle of the application of indicator plants in locating seleniferous soil areas. Further investigation should be made of the selenium content of the initial growth of the various

Stanleya species.

# NEW MEXICO

Plant collections in New Mexico have been made from numerous rock types. Many samples were taken regardless of soil relationships, particularly species of Astragalus. A detailed study was made of the seleniferous plants indigenous to the area just north of Springer, New Mexico. About 30,000 acres of range and irrigated land was included in the survey. The data have been tabulated separately from the other New Mexico areas.

Considerable attention was given to vegetation occurring on soils derived from rocks mapped as Cretaceous and Tertiary in age. A type exposure occurs in the Magdalena section west of Socorro. Marsh and Clawson (14) had indicated from reports reaching them that Astragalus praelongus occurred in the Magdalena region. It was believed to be poisonous to sheep. Since A. praelongus is one of the dominant selenium-absorbing species, it was sought for in this area. Several excursions were made into the Magdalena section during 1938. No Astragali corresponding to praelongus could be found. Marsh and Clawson's (14) statement that Astragalus praelongus and A. sabulosus are synony-

mous is in error.2 Each is a valid type species—A. praelongus Sheld. and A. sabulosus Jones. The latter (10) has a very restricted distribution, being confined largely to its type locality in eastern Utah. Additional search for seleniferous indicator plants on the Tertiary volcanic rocks was continued from Socorro to Las Cruces. None were found. .

In so far as our investigations have gone, it is evident that the geological formations capable of supporting seleniferous vegetation in New Mexico are referable to rock types of Triassic, Cretaceous, and Tertiary age. The principal seleniferous areas

occur in northern New Mexico.

Our field surveys were not planned to cover completely the various geological formations that might support seleniferous vegetation. Many of the formations were not identified in the field. In most instances of this kind the age and rock type have been given.

The geological formations of New Mexico found to be associated with the selenium problem include Mancos shale, Cretaceous undivided, Mesaverde,

and rocks of Tertiary age.

Mancos shale.—The marine mancos shale has vielded faunas (18) of, in ascending order, Green-

horn, Carlile, Niobrara and Pierre age.

Mesaverde Group (also formation).—The typical Mesaverde formation (17) is wholly of Pierre age. It is yet to be determined if this formation is genetically traceable into all the states in which the name has been applied. The Mesaverde formation of southeastern Wyoming is divisible into the marine (lower) and non-marine (upper) members. The marine portion is capable of supporting seleniferous vegetation. The non-marine is not. Whether or not this generalization can be carried into other sections of Wyoming or into other states is not

Pierre-Benton.—These rocks are Cretaceous in age. The name includes the Pierre formation and the Benton shale. Rock types carrying this generalized nomenclature have not been divided into lithological divisions. Seleniferous vegetation collected from areas bearing the name Pierre-Benton cannot be definitely associated with an individual formation such as Thermopolis, Mowry, Frontier, or Pierre. Hence, these rocks are referred to the Cretaceous undivided.

Pierre-Niobrara-Benton .- An assemblage of rocks in which representative formations have not been mapped. It is impossible to state, in areas so classified, whether seleniferous plants were growing on soils of a Niobrara character or some other

type rock falling within the assemblage.

Indicator plants collected from type localities characterized by rocks of Tertiary age in the Aztec-Regina section of New Mexico are seleniferous. The occurrence of seleniferous vegetation on rocks of Tertiary age have not been determined in other areas. In east central New Mexico rocks of Permian

<sup>2</sup> The types have been examined by Dr. Aven Nelson, University of Wyoming. He is satisfied that they are distinct species.

and Triassic age were explored for seleniferous plants early in the spring of 1937. The vegetation was not far enough advanced for adequate sampling. However, the few specimens secured were not found to be selenium bearing. Additional information is needed before conclusions can be drawn regarding the seleniferous character of the rocks of late Permian and lower Triassic age in this area.

A careful investigation of the seleniferous character of the native plants indigenous to the Springer area was undertaken to determine (1) the principal indicator plants, (2) the areas where native grasses were seleniferous, (3) the influence, if any, that native seleniferous plants were exerting on associ-

ated forages and farm crops.

The dominant seleniferous plants of this area are the Astragali. The native grasses are toxic only where these contaminator plants have caused the soil to be enriched with available selenium. Dense stands of Astragalus pattersonii, A. bisulcatus, and A. praelongus occur in the grassy vegas (moist swales). Grass sample, D-365, was taken from one of these vegas. Grass sample D-263 was taken from the edge of irrigated meadow but was growing near seleniferous Astragalus bisulcatus. Grass (same species) sample D-274 was taken from the same meadow but away from the Astragalus influence.

Since the time of this survey the bulk of the seleniferous Astragali in the area inspected have been grubbed out and burned in order to remove the menace that had caused the grasses and other valuable forages to be toxic to livestock. A decided improvement in the livestock in this section was

noted in 1938.

Sophora sericea Nutt., D247; flower; Trace.

# NORTH DAKOTA

A composite sample of Astragalus pectinatus, past seed stage, collected near Beach was seleniferous. Upon analysis it was found to contain 924 parts per million selenium on an air dry basis. The geological formation dominant in the Beach area is the Fort Union (Tertiary). The seleniferous character of A. pectinatus in this section of North Dakota is similar to that obtained for the A. pectinatus samples in eastern Montana on the Fort Union formation and for the same stage of growth.

# OREGON

Dried specimens of Stanleya viridiflora from the Steen Mountain section of southeastern Oregon were seleniferous. In view of the fact that S. viridiflora is generally low in selenium, even on highly seleniferous soils, it is concluded that a more careful study of the indigenous vegetation of this region would be necessary before definite conclusions could be arrived at. The character of the rocks in which the S. viridiflora grew is not known to us.

A few miscellaneous Astragalus specimens from various parts of Oregon were found not to be seleniferous. These included A. sclerocarpus, A. reventors, A. succumbens, and A. howelli. Not any of these Astragali, however, belong to the selenium-absorbing groups.

#### SOUTH DAKOTA

The most dominant and widely distributed native, seleniferous plants of South Dakota are the Asters. The two principal species so far reported on (1, 3, 5) are Aster commutatis T. & G. and A. ericoides L. (Aster multiflorus). There may be additional species still to be determined. The Asters are late in maturing; consequently it is difficult to identify collections previous to the flowering stage.

The seleniferous Astragalus racemosus, A. bisulcatus, and A. pectinatus are rather generally reliable indicators of selenium-bearing soils. A. racemosus has a wider distribution than has A. pectinatus or A. bisulcatus in the areas inspected by the authors. The Stanleya species are excellent indicators of a seleniferous soil, although they are scattered in their distribution. Gutierrezia sarothrae (Pursh) Britt. and Rusby (G. euthamiae T. & G.) has been reported by Moxon (16) and Byers (6) to be rather generally seleniferous. It has a wide latitude of growth and like the Asters may occur on soils free of selenium. Also on some highly seleniferous raw shales, the authors have found this species incapable of absorbing selenium in significant quantities.

Oonopsis argillacea and Xylorrhiza glabriuscula of southwestern South Dakota are confined exclu-

sively to seleniferous soils.

It is not our purpose to review all the plants of this state or any other as to their seleniferous status. We merely wish to point out that certain native plants stand out in their selenium-absorbing properties and that this property is associated with definite geological formations.

The seleniferous areas in South Dakota are associated with formations of Cretaceous and Tertiary age. The Pierre shale (Cretaceous) is the most important exposure in so far as seleniferous soils and plants are concerned. The Fox Hills sandstone and the Pierre formation are stratigraphically equivalent in age to the Steele, Mesaverde, and Lewis formations of central Wyoming.

# TEXAS

Astragalus racemosus and Stanleya pinnata are reported to occur in the high plains country (7) of northwest Texas. Rocks of Cretaceous age (Gulf

series) occur in the Terlingua section of southwest Texas. Stanleya integrifolia, herbarium specimens (1933), mostly stems, from this section gave 525 parts per million selenium. The Gulf series of Cretaceous rocks also occur in east-central Texas from the Rio Grande River to the Red River. However, no selenium indicator plants have been reported in this area (7).

An exploratory survey was made in 1937 in the El Paso-Van Horn-Pecos section for the purpose of determining the presence or absence of seleniferous indicator plants on rocks belonging to the Comanche series. The Comanche series (lower Cretaceous) is believed to be equivalent in age to the lower Cloverly of Wyoming. No indicator plants were found in the areas traversed. Miscellaneous vegetation sampled included a wild Aster, Astragalus missouriensis, Melampodium cinereum, Nerisyrenia camporum, Streptanthus hyacinthoides, a species of mustard, and an Oxytropis. No selenium of consequence was obtained from these several specimens.

#### UTAH

Seleniferous indicator plants in Utah occur in widely separated areas. In the eastern part near Cisco, Xylorrhiza glabriuscula, X. venusta, Stanleya pinnata, and Astragalus pattersonii occur in dense growths. From this area to points above Price the seleniferous Astragali and species of Stanleya may be observed, in patches and in considerable numbers. From Cisco toward Moab, Stanleya pinnata and Astragalus preussii var. latus occur in scattered patches.

The seleniferous shale outcrop in Provo Canyon, east of the City of Provo, has been referred to earlier in this paper. The indigenous vegetation has not been examined critically.

In Box Elder County, northwestern Utah, a sample of seleniferous Astragalus toanus was obtained. In southwestern Utah a large number of seleniferous indicator plants have been collected. The important ones were Stanleya pinnata, Astragalus pattersonii, and A. praelongus.

The geological formations in eastern Utah upon which indicator plants were collected include rocks of Cretaceous and Tertiary age. The two formations of interest, in the areas explored, are Mancos shale (Cretaceous) and Green River (Tertiary). The formation in northwestern Utah was not determined in the field. The seleniferous shale in Provo Canyon is either late Mississippian or early Pennsylvanian in age. The distinctive odor, characteristic of some seleniferous plants, led Dr. David Love, U. S. Geological Survey, Field Assistant, to believe that this formation supported seleniferous vegetation. Dr. Love had previously collected seleniferous vegetation in Wyoming under our direction. Aster glaucus rooted in these shales was seleniferous. Rocks of equivalent age outcropping in other areas in Utah doubtless are seleniferous and should be capable of supporting seleniferous indicator plants.

In southwestern Utah the rocks in which indicator plants grow are believed to be Triassic (Moen-

kopi) in age.

The authors have not made explorations into the southeastern portion of Utah in the pursuit of seleniferous indicator plants. From the nature of the geological formations known to occur, it is expected that certain of the indicator plants should occur in this section of Utah.

No attempt has been made in this report to discuss the geographical distribution of the several plant genera classified by us as selenium indicators. As a matter of fact, this particular phase of the selenium problem was not considered pertinent to the original purpose of our exploratory surveys.

S. paludosus A. Nels., E701; roots; Neg.

Typha latifolia L., E696; roots; Neg.

#### ACKNOWLEDGMENTS

The authors are indebted to the following for aid in assembling this paper: Dr. Aven Nelson and Dr. C. L. Porter, Botanists, University of Wyoming, for the identification of plant specimens; Dr. S. H. Knight, Professor of Geology, University of Wyoming, for his valuable assistance and counsel in the interpretation and presentation of geological data; Dr. S. F. Trelease and Helen M. Trelease, Columbia University, for their collection of indicator plants in several of the western states ("T" and "ET" in lists); Mr. and Mrs. W. Egbert Schenck, Twentynine Palms, California, for their cooperative service; Professor P. A. Munz, Pomona College, California, for collecting Stanleyas in the Mohave Desert; B. W. Allred, Colorado, L. N. Goodding, New Mexico, J. H. Christ, Idaho, Ray E. Miller, Nevada, O. E. McConnell, Wyoming, representatives of the U.S.D. A. Soil Conesrvation Service, for their assistance in supervising the collection of vegetation in their respective districts; Professor J. J. Thornber, University of Arizona, for plant identification; Joseph Arnold, of the same institution, for supplying material from the Verde Valley; Jack Whitehead, Boyce Thompson Southwestern Arboretum, Superior, Arizona, for data on plant distribution; L. E. Coughlin, Wildlife Specialist, U. S. Forest Service, Durango, Colorado, for the collection of vegetation in southwestern Colorado; V. L. Corv, Range Botanist, Sonora, Texas, for information on the distribution of indicator plants in western Texas; Alvin L. Moxon, Station Chemist, Brookings, South Dakota, for cooperative service; Dr. E. S. Perry, Montana School of Mines, for geological data; to Benjamin Clayton, stockman, Springer, New Mexico, for assistance in the collection of vegetation indigenous to the Springer-Cimarron section; and to Carl B. Wolf, Rancho Santa Ana Botanic Garden, Anaheim, California, for *Astragalus limatus* specimens.

#### SUMMARY

Studies were made of 563 specimens of native plants collected from twelve western states. These studies included (1) the geographical location, (2) the rock type, the geological formation and age of the rock or soil on which the specimen was growing, (3) the stage of growth of the plant, (4) the part of the plant analyzed, and (5) the selenium concentration in parts per million. Special attention was given to species of Stanleya, Oonopsis, Xylorrhiza, and Astragalus. The Stanleyas and Astragali, because of their wide distribution, proved especially valuable as indicators. Practically all the specimens of Stanleya were seleniferous. The seleniferous species of Astragali were found to be restricted to five of the twenty-nine groups of Jones' classification of this genus.

These studies demonstrate that numerous geological formations from late Paleozoic to Quaternary in age support native seleniferous plants. These plants are rooted in both igneous and sedimentary rocks. The rocks include monzonite, limestones, and various types of shales. A number of geographical areas and geological formations not previously reported are considered.

# THE RELATIVE HUMIDITY GRADIENT OF STOMATAL TRANSPIRATION <sup>1</sup>

Hiram F. Thut

THE GRADIENT of water vapor from the leaf and through the stomata that accounts for much of the water loss from plants is but little known and one of the least demonstrated phases of transpiration. In this gradient the rôle and value of the relative humidity of the air in the plant tissues in particular have not been demonstrated. Shaw (1935) gives measurements on the relative humidity of the intercellular spaces of some pear and apple twigs. His method of determination is based on the "turgor deficit" of cells. The turgor deficit of the cells was interpreted into terms of vapor pressure. The vapor pressure of the cells and of the air in the intercellular spaces were assumed to be the same, and this value was expressed as the relative humidity of the air. But these measurements based on the assumption that the vapor pressure of the cells and of the air in the intercellular spaces is the same does not give a true picture if transpiration is occurring through these air spaces. There will be a gradient of vapor pressure or relative humidities from the stem tissues through the intercellular spaces to the external air if stomatal or lenticular transpiration is occurring from the twigs. The vapor pressure of the intercellular spaces would thus be intermediate between that of the cells of the stem tissue and of the external air. This condition should also be true for stomatal transpiration from leaves.

The term "turgor deficit" as used by Shaw is synonymous with "suction force" of Ursprung and Blum (1916), "water absorbing power" of Thoday (1918), "suction pressure" of Stiles (1922), "suction tension" of Beck (1928), "effective (net) osmotic pressure" of Shull (1930), and "diffusion pressure deficit" of Meyer (1938). Curtis and Scofield (1933) suggested the term "turgor deficit." The term diffusion pressure deficit will be used in this paper.

Ursprung (1923), Molz (1926), Herrick (1933), and other workers have measured the diffusion pressure deficit of cells. These measurements have been made for various tissues of plants, and the plants have been under various environmental stresses. From these data diffusion pressure deficit conditions or limits of tissues are known. The vapor pressure or relative humidity of the air is a simple physical

vapor pressure gradient from leaves that is responsible for the enormous water losses through stomatal transpiration, a method should be devised that will determine the vapor pressure or relative humidity of the stomatal openings and intercellular spaces.

measurement. To complete an understanding of the

In a recent paper (1938) the author used "humidity bottles" to show the effect of relative humidity on transpiration. Data presented in that paper indicated that such bottles might be used to measure the relative humidity of the stomatal openings and intercellular spaces. For this paper such measurements were made. Small portions of leaves were exposed to various atmospheres of known relative humidity as described and illustrated in the previous paper. A brief description of a humidity bottle will be included here. The base was composed of a glass "preparation" dish having an outside diameter of 50 mm. and a height of 34 mm. Over the mouth of this dish was sealed an aluminum cap by using a rubber paraffin preparation. This cap was previously prepared by having the center raised and a hole of .95 cm. in diameter with an area of .71 sq. cm. punched through the raised portion. The area of the opening was approximately one twenty-fifth of the area of the inside of the "preparation" dish. The opening was stoppered with a tight-fitting cork stopper.

Relative humidity percentages of 100, 90, 80, 65, and 50 were maintained by using sulfuric acid solutions as worked out by Wilson (1921). In the previous work it was found that there was a tendency for the stomata to close over the sulfuric acids maintaining low relative humidities. These concentrations were not included in this series. Only sodium hydroxide pellets were used in the series to maintain a low relative humidity near 1 per cent. Potassium hydroxide was not used as formerly, because the results were similar to those of sodium hydroxide. Sufficient acid solutions or hydroxide pellets were placed in the humidity bottles to have their surfaces two cm. from the openings of the bottles.

After a series of bottles was prepared for an experiment each bottle was weighed on an analytical balance and then supported under the experimental leaf. The stopper was removed, the lower epidermis of the leaf pressed against the edges of the open-

<sup>1</sup> Received for publication February 10, 1939.

ing, and the leaf held in place by glass slide weights. After a period of eight hours the leaf was removed and the bottle stoppered and weighed. Variations in weight of the bottle were interpreted as water loss by the leaf to the bottle or water loss from the bottle to the leaf.

For these experiments potted plants with two definite water balance conditions were used, wellwatered plants called normal plants and wilted plants. The plants were all treated alike up to within a day or two of experimentation. The normal

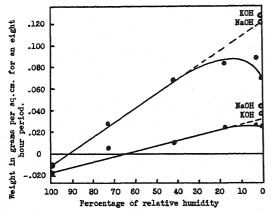

Fig. 1. Water absorption or loss for Lantana. Upper curve for normal plants and lower curve for wilted plants. Each point on the curves the average of six determinations.

or well-watered plants were then set in shallow pans so that a film of water always touched the bottoms of the clay pots. The plants designated as wilted were not watered until the degree of wiltedness was evident. By observation, by weighing the plants and pots, and by the addition of small amounts of water, these plants were held in a constant wilted condition. Most of the experiments were terminated after several days, for differences in the sizes of their leaves became evident.

The data to be presented were all collected in April—that for Lantana in 1937 and the remainder in 1938. The experiments were all performed in the same south window of the laboratory, and the plants were subjected to the temperature and humidity conditions of a classroom in nearly constant use. The temperature averaged 22°C. and the relative humidity from 40 to 50 per cent. The plants were shaded from direct sunlight by a white cloth screen. The humidity bottles were placed in contact with the leaves at 8:00 to 8:30 in the morning and were removed eight hours later. The measurements are thus for plants during that part of the day in which maximum transpiration occurs and during the time the stomata are most open. One eight-hour contact of the bottle with the leaf is designated as a determination.

The first plant used was Lantana Camara, a greenhouse plant, and the leaves experimented upon were mature. The results (fig. 1) were obtained

while data for the previously mentioned paper were being collected. The graph indicates that the water loss from the plants is inversely proportional to the relative humidity. Water losses from the normal and wilted plants are different as indicated by the two curves, the upper curve being the data for the normal plants. As most of the plant is subjected to the laboratory conditions, transpiration will cause a tension to exist in the leaf tissues. This is due to the absorption lag of the roots as explained by Kramer (1938). Those bottles maintaining high relative humidities do not absorb water from the leaf but actually lose water to the leaf because of this tension. The point on the curve where the line passes through the zero line of water loss from the leaf represents in terms of relative humidity the state of the water vapor in the intercellular spaces and stomatal openings. For Lantana the normal plants show a point of 91 per cent relative humidity, and the wilted plants show a point of 65 per cent.

These data for Lantana show the effect on the stomata of using high concentrations of sulfuric acid—i.e., in the region of low relative humidity. There was a marked closing over these concentrations which caused a definite drop in the rate of water loss. The stomata over the hydroxide pellets did not show such marked closing; a possible explanation for this effect was included in the previous paper. The data also indicate that more measurements should be made in the region of higher relative humidity. This was done on other Lantana plants, and the results verify these data.

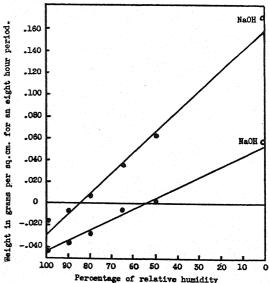

Fig. 2. Water absorption or loss for bean. Upper curve for normal plants and lower curve for milted plants. Each point on the curves the average of four determinations.

The data (fig. 2) for the kidney bean plants (*Phaseolus vulgaris*) were obtained from leaves on the first node above the cotyledons. These data obtained by the experimental series as described earlier are more regular than those for *Lantana*. The

curve for the normal plants passes through the zero line of water loss at 85 per cent relative humidity and that for the wilted at 55 per cent.

For petunia (Petunia hybrida) the data (fig. 3) were obtained from mature leaves on the sixth to tenth nodes above the cotyledons. The results were not so regular as those for bean. The normal plants have the zero point of water loss at 89 per cent and the wilted plants at 79.

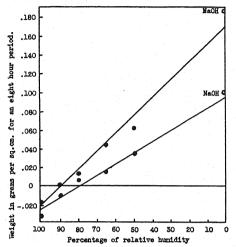

Fig. 5. Water absorption or loss for Petunia. Upper curve for normal plants and lower curve for wilted plants. Each point the average of three determinations.

The sunflower (Helianthus annuus) data (fig. 4) show the zero point of water loss from the normal plants at 94 per cent and for the wilted plants 83 per cent. The leaves on the first and second nodes above the cotyledons were used.

The data presented for these several species of plants are typical of the data obtained by using the

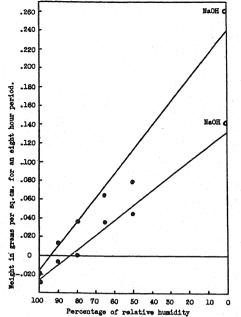

Fig. 4. Water absorption or loss for sumflower. Upper curve for normal plants and lower curve for wilted plants. Each point the average of four determinations.

humidity bottle series. Measurements were made of the diffusion pressure deficits of the several types of leaves by using the "simplified method" of Herrick (1933). Data were obtained for both normal and wilted leaves, and the average result for each set of determinations is shown in the second column of table 1. These data were obtained during the middle of the day, and leaves very similar to those used in the preceding experiments were picked for measurement. The diffusion pressure deficits of these leaves are of the same general magnitude as those

Table 1. The relative humidity gradient of stomatal transpiration as demonstrated by comparing the relative humidity of the leaf tissues, the humidity of the stomatal openings and intercellular spaces, and the humidity of the external air. All figures are averages of several determinations.

Plant and leaf condition	Diffusion pressure deficit of the leaf tissues in atmosphere	Relative humid ity equivalent of the dif- fusion pres- sure deficit of the leaf tissues	Relative humid- ity of the stom- atal openings and intercel- lular spaces	Relative humid- ity of the air about the leaf
Lantana: Normal leaf Wilted leaf		99.4% 98.6	91% 65	40–48% 40–48
Bean: Normal leaf Wilted leaf		99.7 99.5	85 55	44–50 44–50
Petunia: Normal leaf Wilted leaf		99.6 99.5	89 79	42-48 42-48
Sunflower: Normal leaf		99.4 99.2	94 83	42-50 42-50

for other plants as obtained by Shaw (1935), Herrick (1933), Molz (1926), and others. The diffusion pressure deficit values were interpreted into the equivalent relative humidities as worked out by Shaw (1935). The third column of table 1 has the relative humidity equivalents of the cells of the leaves measured.

The fourth column gives the zero points of water loss from the plants as measured by the humidity bottles. These points are being interpreted as the relative humidities of the stomatal openings and intercellular spaces because at these points the humidity of the bottles and of the air in the leaves is apparently the same. The last column gives the relative humidity variations of the air in the laboratory during the experiments as measured by the psychrometer method.

By reading across the table the relative humidity gradient of stomatal transpiration is demonstrated. A normal Lantana leaf showing a diffusion pressure deficit of 10.8 A. has a relative humidity equivalent of 99.4 per cent in its tissues. These tissues are losing water to the intercellular spaces that measure 91 per cent and the spaces to the air of the room that measures 40-48 per cent relative humidity. The wilted Lantana leaf has a relative humidity of 98.6 per cent in the tissues, 65 per cent in the intercellular spaces, and 40 to 48 per cent in the external air. The results for bean, Petunia, and sunflower are similar to those for Lantana. Thus, by this method the several large steps in the relative humidity gradient from leaves can be measured and demonstrated. The relative humidity of the intercellular spaces may be fairly low when the plant is carrying on transpiration and not at or near 100 per cent as has often been suggested.

Ramsay, Butler, and Lang (1938) made measurements of the humidity gradient at the surface of transpiring leaves. They found that a moderately transpiring leaf influenced the humidity to a distance of 2 or more cm. in slow-moving air and that as they approached the surface of the leaf with their hygrometer or evaporimeter, there was an increase in the humidity. Such a leaf caused the humidity of near 50 per cent to be increased above 60 per cent. However, for leaves carrying on low transpiration, they found it nearly impossible to demonstrate a humidity gradient. Their results are substantiated by the results from these experiments. If a moderately transpiring leaf demonstrates a partial humidity gradient outside the leaf, then the humidity of the air within the leaf should be fairly high as is true for these normal leaves. But if there is practically no humidity gradient outside a slowly transpiring leaf, then the humidity of the air within a leaf may be fairly low as is true of these wilted

These results are not without possible error. It was not possible in these experiments to measure the temperature of the leaf and of the humidity bottles. Livingston (1917), Anderson (1936), Curtis (1936), and Leighly (1937) have pointed out

the importance a few degrees of temperature may have on the relative humidities or vapor pressures. Such differences would have a marked influence on the gradient of water vapor to or from the leaves. If differences of temperature existed between the leaves and the humidity bottles, approximately the same differences should be expected through the humidity series. This would not destroy the value of showing the effect of the relative humidity on transpiration even if the whole curve as a result were shifted in position. A shift in the position of the curve would affect the zero point reading of water loss from the plants or, as interpreted, the relative humidity of the stomatal openings and intercellular spaces.

In these experiments the term relative humidity has been used rather than the more desirable term of vapor pressure because of the temperature factor. The humidity bottles maintain rather definite relative humidities but no definite vapor pressures unless the temperature is accurately controlled. These data can easily be changed to vapor pressure figures if the temperature is considered a constant at 22°C.

A second source of possible error would be in the completeness of the seal of the humidity bottle with the epidermis of the leaf. The rims of the bottles usually left a print on the epidermis or cutin, and the seals seemed vapor proof. If, however, leaks occurred, the data obtained would be lower than the actual value, for the bottles would lose water vapor to the relatively drier external air. As a result, the zero point of water loss would be a lower relative humidity figure. However, the definite and constant difference in the results from the normal and the wilted leaves would lead one to believe that if such leaks occur, their influence would be slight. Important leaks would tend to make the results from the two sets of leaves quite similar.

The opening and closing of the stomata was the one factor that might cause the most significant error in these experiments. Many of the stomata, especially of the wilted plants, would close or stay closed. The wilted condition of the leaf as well as other factors may influence the stomata. If a sufficient number of the stomata of the wilted leaves remain open so that a major portion of the transpiration is stomatal and not cuticular, then these results are significant. They show that the relative humidity of the stomatal openings and intercellular spaces, especially of wilted leaves, may be fairly low.

The data presented in this paper demonstrate the diffusion gradient of transpiration even with the consideration of possible errors. Most of all and the fact not previously demonstrated is the intermediate relative humidity of the stomatal openings and intercellular spaces when compared to the tissue losing the water and the air to which the water is lost.

### SUMMARY

The relative humidity gradient of stomatal transpiration was demonstrated by measuring the rela-

tive humidity or equivalent of the tissues of the leaves, the humidity of the stomatal openings and intercellular spaces, and the humidity of the external air. These measurements were made on normal or well-watered plants and on wilted plants. The relative humidities of the tissues were measured by the suction tension or diffusion pressure deficit method.

Measurements were made of the humidity of the stomatal openings and intercellular spaces by noting the effect various relative humidities had on transpiration. This was done by exposing small portions of mature leaves over humidity bottles that contained sulfuric acid solutions or sodium hydroxide pellets. The rest of the plant was exposed to the usual laboratory conditions. The water loss from such leaves was an inverse linear function of the relative humidity. However, in the region of high

relative humidity, water was absorbed from the bottles and not lost. The zero point of water loss from the leaves to the humidity bottles was interpreted as the relative humidity of the stomatal openings and intercellular spaces. The humidity of the air in the laboratory was measured by the psychrometer method.

A normal Lantana leaf showed a relative humidity of 99.4 per cent in the tissues, 91 per cent in the stomatal openings and intercellular spaces, and 40-48 per cent in the external air. A wilted leaf had the figures of 98.6, 65, and 40-48 per cent, respectively. Similar results were obtained for bean, Petunia, and sunflower.

### UPWARD AND LATERAL MOVEMENT OF SALT IN CERTAIN PLANTS AS INDICATED BY RADIOACTIVE ISOTOPES OF POTASSIUM, SODIUM, AND PHOSPHORUS ABSORBED BY ROOTS <sup>1</sup>

P. R. Stout and D. R. Hoagland

THE STUDY of the movement of mineral elements in plants is greatly facilitated by the use of indicator elements which are not initially present in the plant. Bromine and rubidium have been used for this purpose by F. C. Steward<sup>2</sup> in extensive experiments on transport and accumulation. The former element has also been systematically employed in this laboratory as an indicator element. Radioactive isotopes possess certain obvious advantages in following rapid movements of mineral salts, since, first, it is possible to conduct experiments with ions which are known to be involved in the normal physiology of plants, and second, the readiness with which the radioactive isotopes can be detected in extremely small amounts enables one to make observations on small samples of tissues within relatively short periods of time.

With the cooperation of Professor E. O. Lawrence, Director of the Radiation Laboratory, J. P. Bennett of this Laboratory has made a study of the transport of radioactive potassium in the pear tree, and the present writers, also with the cooperation of Professor Lawrence, have conducted experiments on other plants with radioactive potassium, bromine, phosphorus, and sodium, as a development of an investigation of solute movement from root to shoot, especially as influenced by metabolic activities of

the root and by transpiration.

The purpose of this paper is to present experimental evidence on the path of transport of mineral elements in plants after their absorption by the roots through processes involving metabolic activities of living cells. While the prevailing view of botanists is that the mineral elements move upward in xylem tissues as the primary path of movement (cf. review by Mason and Phillis, 1937), this view has been questioned by Curtis (1935). More recently Clements and Engard (1938), following earlier work, have presented strong evidence, based on ringing experiments, in favor of the xylem as the chief path of upward movement of salt, but the problem has been raised again by Gustafson and Darken (1937) in their report on experiments with radioactive phosphate.

By using radioactive isotopes, it was possible to design experiments which, though relatively simple in their general aspect, have provided direct and definite experimental evidence of the path of movement of certain ions in well-developed, foliated plants during periods when factors of light, temperature, and humidity were favorable for plant

growth and for transpiration.

In transport experiments with radioactive phosphorus, Gustafson and Darken (1937) observed

1 Received for publication February 14, 1939.

<sup>2</sup> Private communication.

radioactivity in all parts of the plant whether the plant had a ring of bark or a section of xylem removed. In some of their experiments, Gustafson and Darken removed a strip of bark 5 to 10 cm. long from the xylem of a geranium plant, leaving both ends of the bark attached to the wood. They found less radioactive phosphorus in the detached bark than in the bark which remained in contact with the wood and concluded that there was either an active diffusion of radioactive phosphorus from the xylem into the phloem or that injury attendant on separating the bark had interfered with the transport through it. Their general conclusion was that both xylem and phloem function in upward movement of mineral salts.

The experiments reported here are all "stripping experiments" (fig. 1a). The technique of stripping was similar to that used by Gustafson and Darken and by earlier investigators. With the aid of a Geiger counter we were able to investigate the amount of radioactivity found in a strip of bark in considerable detail and within short periods of time following the absorption by the roots of the ion under study.

If salts are shown to have moved upward in the stem of the plant, and if it is further shown that the salts are present in some tissues of the plant and absent in others, one can be fairly certain that movement did not take place through the tissues in which the salt is found to be absent. Therefore, with the stripping method a possibility should exist for obtaining a clear answer to the question of whether the path of movement is through the phloem or the xylem. The stripping operation can be performed with a minimum of injury to either of the tissues involved and should allow the normal functions of the plant to proceed with the least possible interruption. For example, Mason and Maskell (1928) found that such treatment did not hinder downward movement of sugars and that contact between bark and wood was not necessary for this transport.

EXPERIMENTAL METHOD.—The experimental plants were cotton, geranium, and willow. They were grown in culture solutions [Ca(NO<sub>3</sub>)<sub>2</sub>, .005 M; KNO<sub>3</sub>, .005 M; KH<sub>2</sub>PO<sub>4</sub>, .001 M; MgSO<sub>4</sub>, .002 M] from seedlings of cotton and from small cuttings of geranium and willow. Some geranium p'ants were also grown in sand cultures, so that there would be no possibility of mechanical disturbance of the roots. No difference was observed in the behavior of plants grown in water culture and in sand culture, with respect to salt absorption and upward transport.

A series of experiments was made on the transport of radioactive potassium, sodium, phosphate, and bromide ions. Since each individual experiment produced the same type of evidence, regardless of the species of plant and regardless of the radioactive ion used, it is sufficient for this report to offer two sets of typical data as representative of any of the experiments performed.

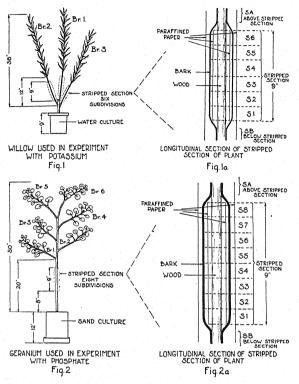

Fig. 1, 1a, 2, 2a. Illustrating the method of stripping bark and of sectioning bark and wood in experiments with willow and geranium plants made for the purpose of measuring movement of radioactive elements.

TRANSPORT OF POTASSIUM IN WILLOW (SALIX LASI-ANDRA) .- A young willow was grown from a cutting in a complete culture solution. The cutting developed 3 branches which were trained upward (fig. 1). The branches extended from the stump 36, 33, and 29 inches, respectively. Two weeks before the experiment, the branches were defoliated for a space of 12 inches above the point of attachment to the stump. Small wounds had time to heal before the bark was stripped. The leaves provided more than 50 per cent of the total weight of the branches when the plant was ready for study. At the beginning of the experiment, the roots of the plant were placed in a 2-liter beaker containing a very dilute culture solution (complete nutrient solution of approximately 0.7 atmospheres osmotic value diluted 100 times) and aerated with a sintered glass aerator. A 9-inch slit was made longitudinally in the bark on opposite sides of branches 1 and 2 (fig. 1a). The bark was then gently pulled away from the wood on each side, and a paraffined paper was inserted between the bark and wood. The entire stripped area was then wrapped with translucent paraffined paper to prevent any loss of moisture. Branch 3 was left intact, but a paraffined paper was wrapped about the outside of the branch as with the first two branches. A fan was turned toward the plant to accelerate transpiration. After an hour and a half the paper between the wood and bark on branch 2 was removed. The bark was bound to the wood with "sterilastic" tape, and the waxed paper was replaced around the outside. Neutral potassium nitrate containing radioactive potassium was then added to the culture solution in an amount to make the solution 5 milligram equivalents per liter in concentration with respect to potassium. After 3 hours of bright sunshine, followed by 2 hours of cloudy weather, the plant was removed and sectioned for analysis according to the diagram (fig. 1a).

All sections were ashed and analyzed for radioactive potassium (table 1). Quantitative technique was observed. The amounts of potassium given in the table were calculated from the measured radioactivity. When the activities were very low, the number of counts was recorded in one-minute intervals, for ten or more consecutive minutes. Only values significantly different from the background when treated statistically are given numerical expression without qualification. The lowest amounts are indicated as less than those which could be de-

tected with certainty.3

The results of the analysis given in table 1 show that after an absorption period of 5 hours, a statistically significant amount of radioactive potassium was found in all parts of the stripped branch (Branch 1, table 1) except the centrally located sections (S2 and S3) of the stripped bark. Wherever the bark was in contact with the wood (SA and SB), the concentration of radioactive potassium was as high in the bark as in the wood immediately in contact with it.

Potassium moved into the bark of Branch 2, which had the bark replaced after stripping, just as readily as it moved into the bark of Branch 3, which was left intact. This was interpreted as meaning that little injury was caused to the bark by the stripping operation.

The analyses of Branch 1 show that the bark above the stripped section (SA) had a concentration of radioactive potassium at least 150 times greater than that of the second or third (S2 and S3) sections of stripped bark. Likewise, the bark below the stripped section (SB) showed a concentration at least 250 times that of bark section S2 and S3. Further, the concentration of radioactive potassium in the wood directly opposite the stripped bark

3 The standard error of the mean of the background was determined by the formula (Snedecor, George W., Statistical Methods, Collegiate Press, Inc., Ames, Iowa, 1937):

$$s \, \overline{x} = \sqrt{\frac{Sx^2}{n \, (n-1)}}.$$

Any value of less than 3 times s x was considered as not significant of the presence of radioactivity in the tissue.

Tain of potassium in sections of willow after absorption period of 5 hours. (Calculated from radioactivity.)

(Section S2 and S3) was at least 300 times greater than that in the bark. Since a gradient of potassium is shown from the upper bark of SA downward through the bark of S6 and S5, it is safe to assume that the potassium found in the uppermost sections (S6 and S5) of the stripped bark moved there from the bark immediately above, and not from the sections below.

PHOSPHATE TRANSPORT IN GARDEN GERANIUM (PELARGONIUM ZONALE) .- A geranium plant was grown in sand culture. At the time of the experiment, the plant was approximately 50 inches high, with 6 well-developed branches (fig. 2). The first 2 branches were 20 inches above the surface of the sand, and the stem below them was kept defoliated for a period of 2 months before the experiment. When harvested, the entire shoot was found to weigh 300 gms. Seventeen per cent of this weight was contributed by the leaves. A 9-inch strip was made 8 inches above the root crown in the same manner as previously indicated for the willow branches. During the operation of stripping the wood was scraped. After stripping, one liter of a dilute culture solution modified to include 1 milligram equivalent of KH2PO4, containing radioactive phosphorus, was added each hour to the sand culture and allowed to drain freely. During the absorption period the plant was placed outside the greenhouse. The weather was fair, with moderate wind. Six hours after the first addition of the radioactive phosphate, the plant was harvested and sectioned for analysis (fig. 2a). After washing the sand away from the roots, they were examined and found to be in good condition as judged by external appearance.

The results of the analysis (table 2) show that after an absorption period of 6 hours, significant amounts of radioactive phosphorus were found in all parts of the plant with the exception of the centrally located sections of the bark on the stripped section (S2 to S4). The concentration of radioactive phosphorus in the bark above the strip (SA)was at least 100 times that in the bark of Section S2 to S4. Similarly, the concentration of radioactive phosphorus in the bark below the strip (SB) was at least 100 times greater than the concentration in the bark of  $S\mathcal{Z}$  to  $\widecheck{S4}$ . At the same time, the concentration of radioactive phosphorus in the wood of S4was at least 300 times that of the bark of S4. As with all experiments performed, there is found a gradient in the bark from the attached ends of the stripped bark toward the central part. It is certain that the relatively high amounts of radioactive phosphorus found in the bark above the strip were brought there by lateral transfer from the wood to which it was attached and not by any upward movement of the radioactive phosphorus through the bark.

The measurements of radioactivity in the central sections of the strips of bark did not attain a level of significance (see footnote 3), and the estimates of radioactivity used for computing ratios represent

Table 2. Gain of phosphorus in sections of geranium after absorption period of 6 hours.

<sup>\* 1</sup> gamma is equal to .001 milligram.

maximum values. Therefore, when a ratio for wood to bark of "at least 100 to 1" is reported, the actual ratio may have been much larger.

It is of interest to note that in a 4-hour absorption experiment with geranium, using radioactive sodium of about ten times the activity of the potassium or phosphorus, we found the concentration in the attached bark above the strip SA (fig. 2) to be at least 1500 times that of the stripped bark of section S3. The attached bark below the strip SB had a concentration of at least 2000 times that of the stripped bark of S3. The concentration of radioactive sodium in the wood of S3 was at least 2000 times greater than the bark of S3. This demonstrates that radioactive sodium, as well as potassium or phosphorus, found in the upper bark SA could have arrived there only through rapid lateral transfer from the xylem immediately attached. In this particular experiment, sodium to a total of 3.4 milligrams or 3400 gammas (calculated from the activity of the sample used) moved from the solution into the plant above the stripped section. Also the wood of S3 gained 76 gammas of sodium, while the bark of S3 gained less than 0.01 gamma. Thus we can state that more than 340,000 times as much sodium had moved past the stripped section into the upper parts of the plant as could be found in the bark of the stripped section S3, while at least 7600 times as much sodium was present in the wood of section S3 as in the bark of this section. It appears conclusive from these data that sodium, potassium, or phosphate must have moved upward through the xylem. If there were any upward movement of these ions through the bark, it must have been comparatively insignificant.

When the stripping technique is used, evidence for the preponderant movement of salts through the xylem becomes less sharply defined with longer periods of absorption. For example, in an absorption period of 20 hours, radioactivity could be detected in all parts of the stripped bark. Nevertheless, a downward gradient in the bark from SA to S3 and an upward gradient from SB to S3 was still demonstrated. The conclusion regarding the relative amounts of radioactive ions moving upward through the xylem and phloem would not be altered.

The observations made after longer periods of time, indicating a slow non-polar movement of small amounts of radioactive potassium, sodium, or phosphorus in the phloem would be in agreement with the evidence reported by Gustafson and Darken (1937). However, the assumption could be made that under the conditions for plant growth prevailing in their experiments, the amounts of radioactive phosphorus moved upward in their plants were extremely small, either because of low absorption by the roots or low transpiration, or both. It is conceivable that if transpiration were greatly decreased by conditions of low light intensity, high humidity, and defoliation, the upward movement of salts with water under the influence of transpiration might be decreased to such an extent that it would not differ greatly from the movement in the phloem. Under these circumstances upward movement of salt might be very slight in comparison with the amounts of salt normally moved upward through the xylem under conditions of active plant growth. The data reported by Gustafson and Darken do not permit an evaluation of the quantity of salt translocated.

Conclusions.—The following interpretations are made of these experiments, and of other experiments which will be presented in more detail elsewhere.

When salts are absorbed by roots, some portion enters the xylem within very short periods of time and is carried rapidly toward the leaves under the influence of transpiration. (In the transpiring plants used in these experiments, radioactivity could always be detected in the uppermost leaves within an hour or less after the radioactive element had been added to the culture medium.) As the salts move upward in the xylem, they are continuously transferred to surrounding living tissues. The amounts of mineral salts which move into the bark by this lateral transfer are far greater than the amounts which normally move longitudinally in the bark. As a result of all the processes of movement, there will occur a general distribution of mineral nutrients in the plant very soon after the nutrients are absorbed by the roots from the soil or other culture medium. The same type of behavior has been demonstrated by radioactive phosphate, potassium, sodium, and bromide ions.

These general conclusions are consistent with those reported by numerous other investigators who used different methods of study. They are also consistent with unpublished experiments conducted in this laboratory from other points of approach to the problem, such as the study of the effects of transpiration on movement of salt from root to shoot and of processes of exudation and guttation. We desire, however, to avoid giving any impression of over-simplification of the general question of salt movement. No attempt is made in this article to discuss the fundamental question of accumulation of salt by living cells of the shoot as influenced by the factors of cell metabolism and growth, and obviously the data presented are incapable of adding to our knowledge of the mechanism of water movement.

### SUMMARY

Radioactive isotopes of potassium, sodium, phosphorus, and bromine were used in studying the upward movement of salt in actively growing and transpiring willow and geranium plants, after absorption of these isotopes by the roots. The technique of isolating a strip of bark from the wood was followed. In this strip of bark the radioactive elements moved extremely slowly. Within short periods of time, no certainly significant amount of radioactivity could be detected in the central section of the strip while large amounts were present in the wood. However, where wood and bark were in contact, radioactive elements were rapidly transferred laterally from wood to bark. The evidence is consistent with the view that the xylem is the path of rapid upward movement of salt.

### DIFFERENTIAL DISTRIBUTION OF ASH IN STEMS OF HERBACEOUS PLANTS FROM BASE TO TIP <sup>1</sup>

### A. E. Edgecombe

In presenting the material of plants to a class of students in botany, it is often necessary to indicate not only the various mineral elements normally present in various parts of the plant but also the quantity and distribution of these minerals in the different regions of the plant. A search of the literature revealed the surprising fact that such a group of data was almost entirely lacking to the student and instructor.

Two sources of literature on this subject were available for consultation. With plants Tukey and Green (1934) had shown for the rose, Rosa multiflora (Thurnb.), that there is an increasing ash content from base to tip of the stem on the basis of <sup>1</sup> Received for publication March 1, 1938.

both dry and wet weight calculations, as well as an increasing water content from base to tip.

The study of ash and water gradients in animals affords an interesting comparison. The studies of Kopenhaver (1937) and Van Deursen (1935) reveal that in an analysis of the body tissues of the worm, Lumbricus terrestris L., on a basis of both dry and wet weight calculations, there is basically a decreasing ash content from posterior to anterior ends of the worm and a decreasing water content from posterior to anterior ends.

Worms, therefore, appear to show a decreasing ash and a decreasing water content from the posterior to the anterior end (Van Deursen, 1935). Roses, however, appear to show an increasing ash

and an increasing water content from the base to the top of the plant (Tukey and Green, 1934). Assuming that the posterior end of the worm parallels the base of the plant and that the anterior end of the worm parallels the top of the plant, the situation then in regard to roses seems the complete reverse of the situation found with worms.

In view of this diverse relationship regarding ash and water gradients in plant and animal, and because so few data on this subject matter among plants are available, the present study was undertaken. This work, however, is limited in its scope to a study of the situation only as it applied to the herbaceous type of plants.

MATERIALS AND METHODS.—The data for these records were obtained from plants grown in the greenhouse under uniform conditions of light, temperature, humidity, and soil composition. One group of plants was grown during the months from September to December, and a second group was grown during the months from January to April.

Two kinds of tobacco plants, White Burley and Big Havana, were used; one kind of cabbage, New Jersey; two kinds of tomato, Bonny Best and John Baer; also Bryophyllum pinnatum Kurz was used to complete the series of plants used in these experiments. All the plants used for experimental purposes were grown from seed for a period of approximately four months.

At the end of the period of growth, the plants were uprooted and freed from soil. Immediately after the removal of the leaves, sections of the stem were taken from the tip, the middle, and the base of the plants. In collecting the sample of tissue from the tip of the stem, the apical sections, each one centimeter in length, taken from ten different plants were pooled to make a single composite sample. The same procedure was used in collecting the samples of tissue to represent the middle of the stem and also those to represent the base of the stem. In each of the three cases, when a sample was obtained, it was immediately weighed and its wet or fresh weight recorded.

The sample so constituted was then dried to constant weight at 100°C. in a thermostatically controlled hot-air oven. This air-dry weight was then recorded. The sample was later ashed to constant weight in a porcelain crucible, and the ash content of the sample recorded. The same procedure was followed in obtaining the wet weight, the air-dry weight, and the ash-content weight of each of the other composite samples of stem tissue—namely, the composite sample made up from ten pieces, each one centimeter long, taken from the middle of the stems, and finally the sample made from the ten pieces collected from the base of the stems.

All three composite samples of stem tissues, taken from the plants grown during the months from September to December, were carried in duplicate sets, and contrasting duplicate sets of tissues were sampled at another season of the year—namely, from the plants grown during the months from January

to April. This procedure was followed for all six varieties of plants used in these experiments.

From the weights so obtained and compiled from these experiments, the percentage ash to dry weight and the percentage ash to wet weight were calculated, and these percentages were made the basis for determining whether an increasing or a decreasing ash gradient existed in plants of the herbaceous types. Following a similar procedure of drying and weighing the selected plant portions, the percentage of water on a wet weight basis was obtained along the axis of the stem.

Table 1. The percentage by weight of the ash content (A.) of the stem to the dry weight (D.W.) and of the ash content (A.) of the stem to the wet weight (W.W.) at the different levels measured in the stem.

% A./W.W	1.38	1.36	1.22
3 Tobacco (Big Havana)			
% A./D.W	7.56	9.71	10.84
% A./W.W	.97	.90	.71

RESULTS AND RECORDS.—In these records only the data obtained from the series of plants grown in the autumn are used here to support the conclusions established by these experiments. While the data, secured by the experiments on the series of plants grown in the winter, are somewhat different quantitatively, they are alike qualitatively and show the same kind of increasing or decreasing ash gradient and, hence, support with equal certainty the general conclusions. Insertion of the second series of data would add nothing to the interpretation or clarification of the problem, and so, in the main, they are omitted entirely.

The results given in table I show that there is an increasing ash gradient from base to tip of the stem when measured on the basis of dry weight and that there is a decreasing ash gradient from base to tip of the stem when the measurement is made on the

Table 2. The same designation as for table 1 with different plants.

basis of wet weight. It was noted further that the data obtained for the second series of plants (winter-grown plants not used in these records) parallel those recorded here.

Examined in the light of the data assembled in table 1, the data recorded in table 2 show the same type of increasing or decreasing ash gradients on the basis of dry or wet weights, thus supporting and confirming the general principles and conclusions already established by the data of the former table.

Table 3. The percentage water content on a wet weight basis.

	Stem	Base	Middle	Tip
1	Tobacco (White Burley)	*87.15 86.46	*91.68 90.06	*92.65 91.17
2	Cabbage (New Jersey)	*66.72 70.38	*71.83 75.21	*83.43 83.13
3	Tobacco (Big Havana)	*87.06 85.59	*89.85 89.18	*94.10 90.11
4	Tomato (Bonny Best)	*86.66 86.99	*90.72 89.23	*91.95 91.67
5	Bryophyllum pinnatum	*89.45 87.39	*94.23 92.66	*94.88 95.04
6	Tomato (John Baer)	*84.83 88.62	*87.10 89.09	*93.34 92.83

The upper numbers of the two series of figures for each plant, starred (\*) in table 3, represent the results obtained from the experiments on plants grown in the autumn. The parallel sets of figures recorded in the lower one of the two series of figures for each plant, not starred in table 3, were obtained from the experiments on plants grown in the winter. In all instances the experimental results for herbaceous plants indicate an increasing water content from base to tip of the stem.

The experimental data assembled in table 4 show that the percentage ash content, figured on a dry weight basis, and the water content, estimated in percentage on the basis of wet weight, parallel each other in both herbaceous and rose plants (Tukey and Green, 1934), thus showing in both instances an increasing ash and water gradient from base to tip of the stem. On the basis of wet weight, however, the ash content for herbaceous plants, estimated in percentage, is reversed.

A further examination of the data summarized in table 4 shows that the percentage gradients of ash for herbaceous plants on the basis of dry weight and the percentage water content on the basis of wet weight are exactly opposite to the gradients on the same basis for worms (Van Deursen, 1935), the plant showing increasing, the worm decreasing gradients. However, the percentage gradient of ash for herbaceous plants on the basis of wet weight follows the same order as the percentage gradient of ash for worms, both showing decreasing gradients.

Discussion.—The aim of this investigation is to discover and interpret the distribution of the ash content of herbaceous plants along the stem from base to tip, when calculated on the basis of dry weight and also on the basis of wet weight. The distribution of the water content along the stem on the basis of wet weight is also included.

While work is in progress to determine, if possible, on a qualitative basis the kinds and gradient distribution of the common mineral constituents present in the ash, the experiments reported in this piece of research deal entirely with the ash content on a purely quantitative basis, and no attempt has been made to use the tentative data already obtained on calcium distribution to figure in these interpretations.

In view of adequate data obtained in this investigation and summarized in tables 1 and 2, it seems fairly evident that there is a definite ash gradient in herbaceous plants on the basis of dry weight, increasing from base to tip of the stems. These results agree in principle with the results obtained by Tukey and Green (1934) from an ash analysis of roses. They found an increasing ash gradient on the basis of dry weight in the one-year-old stems of a species of field-grown rose, Rosa multiflora (Thurnb.), that had been propagated by cuttings.

Table 4. Comparison of summary data in rose, herbaceous plant and worm. Key to symbols: A = % ash; W = % water; D.W = dry weight; W.W = wet weight; 0 = middle weight; + = increasing gradient; - = decreasing gradient.

	•	Middle				Middle	0	0	
		Base	-	+	<u></u>	Posterior	+	+	+

The data recorded in tables 1 and 2 show, on the other hand, that on the basis of wet weight there is a decreasing ash gradient from base to the tip of the stem in herbaceous plants. This finding differs from that obtained by Tukey and Green (1934) in their work. They found for roses an increasing ash gradient, calculated on the basis of wet weight. This finding paralleled the increasing ash gradient that they found for roses on the basis of dry weight.

As is indicated in table 3, there is sufficient evidence of a confirmatory nature to support the conclusion that in herbaceous plants there is an increasing water content from base to tip of the stem, calculated in percentage on a wet weight basis. A parallel increasing water gradient is shown by Tukey and Green (1934) for the stems of rose plants. The increasing water content appears to be due in some way to the water associated with the greater amount of mobile protoplasm in the living tissues that increases from base to tip of the stem in herbaceous plants.

The data summarized from the thesis of Van Deursen (1935) are compared with the summary data found by the writer through experimental investigations on herbaceous plants. The comparative data are assembled in table 4 and represented by "plus," "minus," and "zero" symbols. The data show for worms a uniformly decreasing gradient for ash on the basis of body dry-weight, also a decreasing gradient for ash and water on the basis of body wet-weight, when calculated on a percentage basis from posterior to anterior parts of the worm.

These data seem to indicate, in general, a reversal of gradient for ash and water content in worms, measured from posterior to anterior ends on a percentage basis as compared to the gradients for ash and water on the basis of dry and wet weight in the stems of herbaceous plants, where in two instances there are increasing gradients. However, considering that the growing region of the worm is toward the posterior end, it is then not so surprising to find an increasing ash and water content appearing in that direction, particularly so since the metabolic gradient in the worm progresses from the anterior toward the posterior end. If, therefore, the metabolic gradient is from base to tip in the plant, the growing region in those plants examined being toward the tip, then the reversal for ash and water content in worm and plant is not a contradictory phenomenon but a similar behavior, since in each instance the increasing ash and water content is correlated with and parallels the metabolic gradient and also increases in the direction of growth for both plants and worms.

The data for rose plants, abstracted from the article by Tukey and Green (1934) are contrasted with the summarized data of the writer for herbaceaus plants and show for roses a uniformly increasing gradient for ash on the basis of dry weight and also for ash and water on the basis of wet weight. These data seem to indicate, in the main, that the gradient values for herbaceous plants, as is

indicated in table 4, follow a parallel course to that of rose plants. Only in the case giving the ash value on the basis of the wet weight is there a decreasing gradient for herbaceous plants.

In general, then, it appears that the increasing ash content for herbaceous plants, from the base to the tip of the stem, is due, in part, to a greater accumulation of such materials as carbohydrates and fats at the base than at the tip of the stem, which materials contain less minerals, and in part, at least, to an increased accumulation of protoplasm toward the tip of the stem apparently accounting for the increase of ash content in that region.

### SUMMARY

Six different species of herbaceous plants, developed from seeds, were used in this investigation. These plants were grown under uniform conditions for four months in the greenhouse. Spring and winter groups of plants were examined separately for comparisons.

All tests were made in duplicate, and to preserve uniformity of tissue throughout, composite samples of plant materials, taken from specific regions of the stem, were used in the experiments.

The wet or fresh weight was taken on an ordinary balance at the time the stem tissue was collected. The dry weight at 100°C. and the ash weight of the tissue after incineration were taken on precision balances. The water content was calculated from the wet and dry weights.

When samples of stem tissue were taken from the base to the tip of the plant, an increasing ash gradient on the basis of dry weight, a decreasing ash gradient on the basis of wet weight, and an increasing water gradient on the basis of wet weight were uniformly obtained.

In general the ash and water gradients, determined for herbaceous plants, are the reverse of those found for worms, except for the ash content on the basis of wet weight where there seems to be a parallel situation, or similarity of findings for both plant and worm.

The ash content on the basis of dry weight and the water content on the basis of wet weight, however, for both plant and worm, are correlated with the metabolic gradient and parallel the direction of growth in these organisms.

In the main, the ash and water gradients determined for herbaceous plants are of the same order and direction as those found for rose plants, except for the ash gradient on the basis of wet weight, where there seems to be a dissimilarity of findings for herbaceous and rose plants.

### THE RELATIVE ACTIVITIES OF DIFFERENT AUXINS 1

Kenneth V. Thimann and Charles L. Schneider

Now that so many substances have been found to behave as auxins in promoting the growth of plants, it becomes of increasing importance to be able to compare their activities with some precision. This is particularly necessary in any study of the relation between structure and activity. It has been pointed out earlier (Koepfli, Thimann, and Went, 1938) that the mere presence or absence of growthpromoting activity is sufficient criterion for a first attack on the problem, but the quantitative comparison of activities introduces additional complexities. This is in part due to the fact, first elucidated by Thimann (1935), that the relative activity of any substance, compared to another substance as standard, varies according to the method of assay. Thus, even if the most fundamental physiological property of auxins-namely, growth promotionwere used, Thimann found that indene-acetic acid had only 1 per cent of the activity of indole-acetic acid by the curvature method, but about 7 per cent by straight growth. The test object was the Avena coleoptile in each case. When tests based on root initiation or bud inhibition were compared, the influence of the method of assay was still more marked. Other examples of the same principle may be seen in the table of Went and Thimann (1937, p. 137) which summarizes the activities of numerous auxins found by various investigators with different meth-

We have recently had occasion to compare the activities of some pure auxins and related compounds on straight growth and on curvature, using the same test plant and also different plants. The results and conclusions form the subject of this note.

Materials and methods.—The following seven compounds were studied: indole-3-acetic, -propionic, and -butyric acids; benzofurane-3-acetic, 2 alphanaphthalene-acetic, 3 phenyl-acetic, and gammaphenyl-butyric acids. Of these compounds, only the indole and naphthalene derivatives give definite auxin curvatures in the standard Avena test (see table XII of Went and Thimann, 1937), though the other substances may give small curvatures, both positive and negative, at longer intervals after application.

The methods used were (1) direct measurement of elongation of isolated sections of Avena coleoptiles and of Pisum stems (method of Bonner, 1933,

1 Received for publication March 4, 1938.

<sup>2</sup> Synthesized by Titoff, Muller, and Reichstein (1937). <sup>3</sup> Sample of high purity prepared by Dr. Franklin Jones, Chemical Paint Company. with modifications of Schneider, 1938) and (2) curvatures of slit *Pisum* stems (method of Went, 1934, with modifications of Thimann and Schneider, 1938). The coleoptiles were used at an age of 75–77 hours from soaking. The peas were aged about eight days, the third internodes used being then well developed but still growing. Three sections each 3 mm. long were cut from each plant, beginning at 5 mm. below the tip in *Avena* and about 10 mm. in *Pisum*. With *Avena*, not less than 10 plants—i.e., 30 sections—were used for each solution tested. With *Pisum*, 15–25 sections were found sufficient.

For the slit stem curvature, about 1 cm. was cut off the tips and the zone below it halved longitudinally for a distance of 3 cm. Unless otherwise stated, the sections and slit stems were immersed in shallow layers of the test solutions directly after cutting.

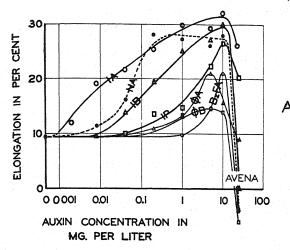

The plants were grown and tests carried out in a physiological darkroom at 24°C. and 85 per cent relative humidity with only occasional red light. Under these conditions, by far the largest part of the elongation and curvature of the tests was completed in 24 hours. Measurements were made at 30–60 hours. For the sake of completeness, some curvature measurements in the *Avena* test are also included.

RESULTS AND CONCLUSIONS.—Figure 1A shows the activities of the different auxins as determined by straight growth of sections of Avena coleoptiles. It represents the average of two separate experiments performed on different dates but showing close agreement. Each experiment involved 38 solutions and a total of more than 1100 coleoptile sections. A third experiment, which did not include as many concentrations, is incorporated into the points at 1 and 5 mg. per liter and also gives the points at 25 mg. per liter. The concentrations around the optimum were studied again in a separate experiment. These data are plotted on an arithmetical scale in figure 1B. From both figures it is clear that the optimum concentration for each auxin is not far from 10 mg. per liter. It will be noted that indoleacetic acid exerts growth-promoting activity at a much lower concentration than any other substance and that the curves for the three-indole acids are well separated.

Figure 2A, also the average of two complete experiments, shows similar results for the straight growth of *Pisum* stem sections. Comparison of the two figures shows that for all auxins, except per-

haps indole-propionic acid, Avena shows detectable increase in growth at lower concentrations than Pisum. Similarly the optimal concentrations are on the whole lower for Avena than for Pisum, for in the latter definite toxicity does not appear up to 25 mg. per liter (see also fig. 7 of Thimann and Schneider, 1938). The whole range of effective concentrations in Avena is thus from two to five times as low as in Pisum.

With regard to relative activities, it is clear that the auxins fall in about the same order in both cases,

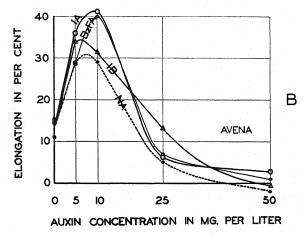

Fig. 1.—A (above). Elongation, as percentage of their initial length, of 3 mm. sections of *Avena* coleoptiles in solutions of different auxins. Lettering of curves (as in all other figures):

IA, indole-3-acetic,IB, indole-3-butyric,

NA, alpha-naphthalene-acetic,

IP, indole-3-propionic,

 $\phi A$ , phenyl-acetic

 $\phi B$ , gamma-phenyl-butyric,

BzFA, benzofurane-3-acetic acid.

but there is a considerable quantitative difference between the two plants. The curves for the indole acids are much more widely separated for Avena than for Pisum. On Avena, indole-acetic is about ten times as active as indole-butyric and 100 times

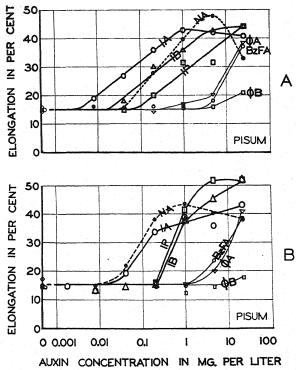

Fig. 2. Elongation, as percentage of their initial length, of 3 mm. sections of etiolated *Pisum* internodes.—A (above). Mean of two series of curves (Mar. 28 and Apr. 13, 1938).—B. Experiment of May 4, 1938. The values for the four sets of water controls are plotted separately to give an indication of their close agreement. Same auxins as figure 1.

as active as indole-propionic, while on Pisum the corresponding values are about four times and sixteen times, respectively. It is interesting to note that the activity in straight growth alternates with increasing length of the side-chain, in the same way as has been found for the standard Avena test (Went and Thimann, 1937, p. 137). Further, phenylbutyric acid shows activity at 1 mg. per liter on Avena but not below 10 mg. per liter on Pisum. In one or two of our experiments, phenyl-butyric acid showed no activity at all on Pisum. The relation between the curves for a-naphthalene-acetic acid and indole-acetic acid is the same as that reported by Scheer (1937) in straight growth measurements of Avena, made by symmetrical application of agar blocks for eight hours. Her curve for naphthaleneacetic acid is lower than that for indole-acetic acid at low concentrations, but the curves cross at 0.3 mg. per liter. Ours cross at 0.1 mg. per liter (fig. 1A). In general it is clear that not only absolute activities but the relative activities of the different auxins, compared to indole-acetic acid as standard,

depend on the test plant used.

Relative activities also depend upon some factor more difficult to define. Figure 2B shows another series of experiments on the elongation of Pisum sections, using the same auxins. The curves differ considerably from those of figure 2A. The minimal concentrations giving increased growth are higher and the slopes of the curves in the zones where growth is a function of auxin concentration are much greater. In addition, the relations of the auxins to one another are considerably changed. The curves for indole-butyric and -propionic acids, instead of being well separated, almost coincide, while indoleacetic acid is less active than naphthalene-acetic acid over the whole range. Two considerations show that these variations are real: (1) each point is the mean of 15-21 sections, the range of distribution of whose individual growth values is far less than the difference between two corresponding points, and (2) the points on each curve support one another, so that the differences are between whole curves and not just individual points. Of the four complete experiments performed, two gave results which agreed well and are averaged in figure 2A, one gave the data of figure 2B, and the other gave results divergent from both, but somewhat resembling those of figure 2B. The differences could not be correlated with any observable differences either in the plants used or in the lengths of the internodes at the time they were taken. Similar differences in relative activities on different days have been found with straight growth of Avena coleoptile sections.\* Such variations are fairly large, and, as may be seen, introduce both quantitative and qualitative differences. The causes are obscure but must comprise some superficially minor differences in the conditions or the treatment of the plants. It is evident, however, that the relative activities of different auxins vary not only with the plants used, but also with their sensitivity on the day of the test.

Figure 3 shows the results of three complete experiments (A and B) on slit stem curvatures ("pea test" of Went, 1934). Each involved about 250 individual curvatures. Measurements are by the "stem reference" method (see Thimann and Schneider, 1938). The most obvious difference between these data and those above on straight growth is that here there is little consistent difference between the activities of the four most active auxins, supporting the statement previously made about this test that "indole-3-acetic, indole-3-propionic, indole-3-butyric, and alpha-naphthalene-acetic acids at low concentrations approach the same activity per mol" (Went and Thimann, 1937, p. 135). If one takes the average of all the data, the differences between the

\*The same phenomenon occurs even in the standard Avena curvature test. The relative activity of indole-butyric acid, determined by this test, varied on different days between the limits of I per cent and 15 per cent of that of indole-acetic acid.

activities of the three indole acids, which are so marked in figure 1, practically disappear.

It has been shown further by D. Bonner (1938) that if correction is made for differences in dissociation constants, the activities of a number of auxins, but not all, approach one another closely. It is clear from figure 3, however, that in individual experiments the activities of different substances are in no case truly identical. The same evidently holds for figure 6 of D. Bonner (1938).

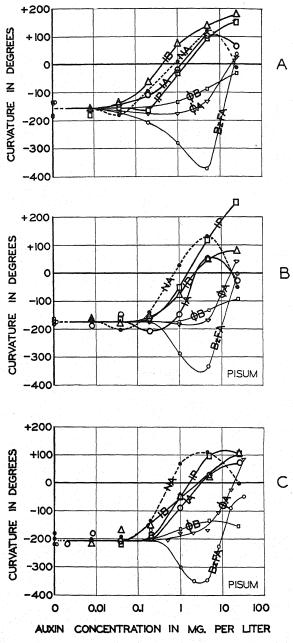

Fig. 3. Three measurements of auxin activity by means of slit stem curvatures with *Pisum*. Same auxins as figure 1 (Mar. 28, Apr. 14, and May 4, 1938).

Table 1. Concentrations of different auxins giving minimal and maximal responses of straight growth and of slit stem curvatures with Pisum.

	Conc	entration in m	g. per liter gi	ving:
	Just detect- able straight growth	Just detect- able inward (or decreased outward) curvature	Maximum straight growth	Maximum inward curvature
Indole-acetic (IA)           Indole-propionic (IP)           Indole-butyric (IB)           Naphthalene-acetic (NA)           Phenyl-acetic (\$\phi\$A)           Benzofurane-acetic (BzFA)		0.35 0.23 0.10 0.12 3	14 20 11 4 25 25	12 20 25 5 25 25

Comparison of the absolute concentrations in figures 2 and 3 brings out a second point—namely, that each auxin (except perhaps phenyl-butyric acid) causes increase in growth at concentrations below those which cause inward curvature (see table 1). Phenyl-butyric acid behaves exceptionally on certain days, however (see below). In contrast, the concentrations which cause maximal straight growth agree very well with those causing maximal curvature.

It is perhaps worth noting that indole-acetic and naphthalene-acetic acids, in which the differences between the two threshold concentrations are greatest, are the two which give outward curvatures most frequently and regularly.<sup>4</sup> Their behavior comes nearest to that of benzofurane-acetic acid (see below) in this respect.

These facts are readily explained by consideration of the nature of curvature and of growth. Inward curvature occurs when the growth of the outer layers exceeds that of the inner (Jost and Reiss, 1936; van Overbeek and Went, 1937). However, as we have previously shown (Thimann and Schneider, 1938) for indole-acetic and benzofurane-acetic acids, in the lowest auxin concentrations it is the innermost layers which respond more than the outer. Nevertheless, the maximum increase in growth of which the inner layers are capable is small, and hence at higher concentrations the outer layers grow more than the inner, causing inward curvature. Before this concentration is reached there is an intervening range in which the growth rates of both tissues are increased. In this range, therefore, the stem shows increase in straight growth. Thus straight growth will in general be increased at concentrations lower than those which cause inward curvature.

The case of benzofurane-3-acetic acid is rather exceptional in that, as we have previously shown (Thimann and Schneider, 1938), it promotes growth of the inner layers at concentrations very much

<sup>4</sup> The production of increased outward curvatures by auxin concentrations too low to cause inward curvature was described in the preceding paper (Thimann and Schneider, 1938).

lower than those which affect the outer layers. However, there is no reason to believe that growth of a single tissue or layer suffices to cause marked growth of the whole stem. Since with benzofurane-acetic acid only the growth of the inner layer is promoted by low concentrations, marked straight growth does not begin until the growth of the outer layers is increased. This will be where the curve (fig. 3) reaches its lowest point and begins to turn upward, or at about 2–5 mg. per liter (cf. table 10 of Thimann and Schneider, 1938).

Special consideration must also be given to the action of y-phenyl-butyric acid. This substance, scarcely an auxin in the strict sense of the word, since it is almost inactive in the standard Avena test, has in some tests shown a reduction in outward curvature at concentrations lower than the minimum for straight growth. Of a total of 10 complete experiments, each with serial dilutions, either of the acid or its Na salt, curvature was shown at the same concentration as growth in 5, at lower concentration in 4, and at higher concentration only in 1. When curvature is influenced by a concentration which produces no growth, explanation is difficult. It might be suggested that the effect is the reverse of that of benzofurane-acetic acid-namely, that the outer layers respond to lower concentrations of phenyl-butyric than do the inner layers. This, however, is improbable under normal conditions, because, owing to the tension of the outer layers, any increase of their length should allow a corresponding elongation of the inner layers and hence straight growth. A second possibility—namely, that the growth of the inner layers is actually inhibited—was ruled out by direct measurement of the elongation of isolated layers of tissue and also of the inner and outer sides of the slit stem. Neither of these measurements showed any inhibition of the growth of the inner tissues at concentrations which give slight or definite inward curvature. It is worth noting that the difference between the growth of the two sides of the slit stem (o-i in fig. 4) was found to be linearly proportional to the curvature, and the proportionality was the same for phenyl-butyric as for indole-acetic acid.

The difficulties of reaching a conclusion are increased by the small magnitude of the effects of phenyl-butyric acid. Where growth is small and experimental error, therefore, large, curvature is a more sensitive response than straight growth measurement. On days when the growth and curvature

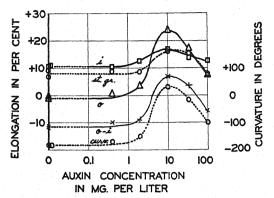

Fig. 4. Gamma-phenyl-butyric acid. Direct measurements of length of the inside (i) and outside (o) of slit halves of *Pisum* stems compared with independent measurements of straight growth (sb. gr.) and of curvature. Mean of two complete experiments (Aug. 24 and Dec. 3, 1938).

are relatively large there is excellent agreement between the two, as shown in figure 4. It is, therefore, very doubtful whether these apparent anomalies have any real significance.

Thus, for all the auxins studied, the essential characters of these curves fit in with the concepts we have previously developed and provide additional support for them. The recent experiments of Jost (1938) also confirm completely our explanation of the inward curvatures.

The three experiments of figure 3 give a sample of the variation found between different slit stem tests.

Since it is possible that the amount of auxin still in the stem after cutting influences the response to applied auxin, some tests were carried out in which the sections were cut off, placed in water for four or even eleven hours, and then transferred to auxin. This treatment, however, merely reduced the absolute curvatures somewhat. Even phenyl-butyric acid, which is practically inactive in the Avena test, still gave inward curvatures on slit stems that had been kept eleven hours in water.

It is an interesting corollary that the difference in sensitivity to auxin of two layers of tissue within the same plant is itself comparable to the differences in the sensitivity of two different plants. Thus the Avena coleoptile is sensitive to lower concentra-

<sup>5</sup> In figure 4 the straight growth is the average of four 5 mm. sections from each plant—i.e., the same zone of about 20 mm. over which the "inside" and the "outside" measurements were made. This results in a lower growth response than if three 3 mm. sections had been used as above; thus the water controls grow only 8 per cent as against 15 per cent in figure 2.

tions than Pisum but gives less absolute elongation—i.e., it behaves somewhat like the inner layers of Pisum.

Although the elongation of Avena coleoptile sections is increased by sugar, this is not as a rule true for Pisum sections, as we have previously found. This suggests that the differences in the behavior of Pisum and Avena might be due to differences in carbohydrate supply. Straight growth measurements were therefore made on Avena in presence and in absence of sugar. Although the total growth was increased throughout, the positions of the curves for the different auxins (the three indole-acids and benzofurane-acetic acid were used) remained the same and the relative activities were almost unchanged. The carbohydrate supply, therefore, is not the important factor responsible for the differences between the two test plants.

VALUES FOR RELATIVE ACTIVITIES.—It follows from the above that relative activities of different auxins vary with the test plant, test method, and the sensitivity.6 These facts make it very difficult to assess relative activities quantitatively. In table 2 the averages of our observations with the different test methods are summarized. All are expressed as percentages of the activity of indole-acetic acid. The activity for straight growth is determined by the highest dilution which produces 50 per cent greater elongation than that of the water control. That for slit stem curvatures is similarly determined by the highest dilution which decreases the outward curvature by 100° when measured by the "stem reference" method. (These values are in good agreement with those determined from the dilutions which give a curvature of 50° by the "inflection reference" method.) These dilutions (or reciprocal concentrations) are then expressed as percentage of that dilution of indole-acetic acid which has the same effect. The values for curvature in the standard Avena test are in part new determinations, in which several times of application of agar blocks, from 90 to 150 minutes, were used, and are in part taken from Went and Thimann (1937).

The important points to be noticed in the table are: (1) the numerical values vary widely with the test method, (2) the order in which the auxins fall is the same for the two straight growth methods, (3) relative activities are, throughout, lower for Avena straight growth than for Pisum straight growth—i.e., the Avena coleoptile is the more "specific" (i.e., discriminating) object, and (4) as has been made clear by the earlier work, the standard Avena test using agar is much more specific still.

It is evident that such differences as those above amply account for the discrepancies between rela-

<sup>6</sup> Van Overbeek (1938) makes the following statement: "An auxin amount expressed in hetero-auxin equivalents is independent of the test method, test plant and sensitivity." This, it will be clear, is not borne out by our experiments, nor, apparently, by the experience of Ferman in Utrecht (see Ferman, 1938).

a Data from Went and Thimann.

tive activities found by different workers. Differences in the purity of samples used may also account for some of the discrepancies which have been reported. Further, when one considers that the variations described here are found with uniform plants grown and used under carefully controlled conditions, it is clear that data obtained with less critical material, such as with green plants under greenhouse conditions, have little quantitative significance.

The fact that each auxin has its own characteristic curve in the different tests could conceivably be turned to advantage for the identification of an unknown auxin. Both the shape of the curve and the relative activity in different tests could be used as identifiable characters.

### SUMMARY

Although it is well known that different substances have different activities as auxins, it is often

thought that the ratio between the activities of any two substances would always be the same. In this paper the activities of six different pure auxins in promoting growth were compared with that of indole-3-acetic acid as standard. The ratio between the activity as determined by any method and that of indole-acetic acid in the same method is termed the "relative activity." Relative activities for straight growth as determined on Avena coleoptiles differ from those determined on Pisum internodes. The differences between these two plants are not due to differences in carbohydrate supply. With Pisum the values for straight growth differ from those for slit stem curvatures. This is explained on the basis of differential sensitivities of tissues within the plant. With any of the methods, the values also vary somewhat with the sensitivity of the plants on the day of the test. By taking the mean of several series of experiments with each method, approximate relative activities have been derived and tabulated.

### THE EFFECT OF DEHYDRATION ON MICROSPOROGENESIS IN TRADESCANTIA $^{\scriptscriptstyle 1}$

### Norman Giles

Numerous studies have been made of the effect of various agencies such as chemicals, abnormal temperature, radiation, and genetic factors in producing abnormal nuclear and cell division. Experimental observations have been made on both living and fixed material. In general it is found that many distinctly different agents produce similar effects, of which the majority seem to result from a disturbance of the normal synchronization of the cell's activities during the division cycle. Reviews of the experimental study of nuclear and cell division include those of Politzer (1934) and Küster (1935).

Recently the importance of an adequate cellular water content for the normal course of somatic nuclear and cell division has been demonstrated by the work of Wada (1936a, 1936b) on stamen hairs and Shigenaga (1937) on petal cells of Tradescantia L., and by Milovidov (1938) working on root tips of Vicia faba L. Oehlker and his students, in a series of papers dealing with studies in the physiology of meiosis, have investigated the effect of dehydration, occasionally in combination with high and low temperatures, as indicated by variations in chiasma frequency at diakinesis in Vicia faba, Campanula percifolia L. (Straub, 1937), and various species of Oenothera L. (Kisch, 1937). These studies indicate that the degree of hydration of the cell is a controlling factor in the normal synchronization of chromosome behavior and nuclear and cell division. The present investigations deal with the effect of dehydration upon cellular phenomena during microsporogenesis in Tradescantia.

MATERIALS AND METHODS.—During the course of an investigation of the effect of certain chemicals such as saponin and colchicine on meiosis in Tradescantia, it was noted that the control stems with paraffin sealed ends showed the same abnormalities as the chemically treated stems. This observation led to a more detailed study of the effects of water deficiency. Plants of a clonal line of a hybrid derived from Tradescantia canaliculata Raf. and a clonal line of T. paludosa Anders. & Woods. were used. Flowering stalks were cut and the ends sealed and coated with warm paraffin to a distance of about one cm. up the stalk. These stalks were then placed in water maintained at a level of about three cm. in containers kept in the greenhouse. In some cases the paraffin was removed from the stalks after a certain time and the free ends left in the water. In others the paraffin was left intact for the duration of the experiment. In the latter cases evidently the stems were often able to obtain some water, for some stalks

<sup>1</sup> Received for publication February 14, 1939.

The writer wishes to acknowledge his sincere appreciation to Prof. Karl Sax for suggestions and criticisms during the course of this work.

developed roots which broke through the paraffin. Obviously the methods used did not give any definite or uniform indication of the amount of water received by the stem. However, this was not an essential factor, since the aim was simply to study the effects of a general dehydration on meiosis and related phenomena. A few observations were also made on entire potted plants which were not watered for several days. As controls, cut stalks with unsealed ends were placed in containers of water and kept in the greenhouse. In no cases were abnormalities observed in these. Acetocarmine smear preparations of the anthers were made at intervals in order to study the effect of the restricted water supply upon meiosis and the microspore division.

Observations.—Nuclear division.—Apparently the effects of dehydration on nuclear division in Tradescantia are similar to those produced by temperature (Sax, 1937) and colchicine treatment (Walker, 1938). The restriction of the water supply results in the suppression of the spindle mechanism at the first or second meiotic division, thus preventing the normally paired chromosomes from passing to the poles. Apparently the chromosomes then reassemble into a single nucleus and proceed to divide equationally to produce dyads with the diploid number of 12 instead of the haploid number of 6. In some cases both nuclear divisions are inhibited, the 12 chromosomes resulting from the first equational division then dividing again equationally, thus producing 24 univalents organized into a tetraploid. The suppression of either the first or the second meiotic division results in the production of two diploid microspores which undergo normal mitosis at the microspore division (fig. 3, 4). The tetraploid monads also divide normally at the microspore mitosis (fig. 6, 7).

The cytological effects of sealing off the stems were first noted after 11 days. The cells were then in the young microspore stage just after the second meiotic division. The experiments were carried out in February and March, at which season the duration of the meiotic cycle is increased from the normal summer period of about a week (Sax and Edmonds, 1933) to one of about two weeks' duration (from early prophase to the stage when the young microspores begin development). These time relations seem to indicate that the interruption of the water uptake was not immediately effective in upsetting nuclear divisions already in progress at the beginning of the treatment. Apparently a certain degree of dehydration of the cells is necessary before spindle inhibition and other abnormalities result. The indications are that only those cells that were in the early stages of meiotic prophase or earlier at the start of the treatment were affected at the time of the first meiotic division.

There seems to be no constancy in the effect of dehydration in any single anther or group of anthers. The percentage of abnormalities may run as high as 75 per cent in one anther, while in another anther of the same flower there may be no irregularities at all. Haploid, diploid, and other polyploid microspores may occur in the same anther, but the normal haploid spores are almost always the most abundant. The monads are also less common than the dyads.

In one anther several giant pollen grains were observed 22 days after the paraffin treatment (fig. 5). Since none of these were seen at microspore division, no chromosome counts were obtained. However, the size of these grains as compared with that of the tetraploids indicates that their number is probably 48 or octoploid. It appears that pollen of this type results from chromosome doubling through spindle inhibition in premeiotic cells followed by two chromosomal but no nuclear divisions at meiosis as is the case when monads are produced. It has also been found that such octoploid cells are produced in *Tradescantia* by colchicine treatment (Walker, 1938).

Obviously the effect of dehydration in inhibiting nuclear division by suppressing the spindle is reversible as the chromosomes can reassemble into a polyploid nucleus which goes through succeeding divisions in a normal manner. In cases where dehydration was very intense the entire stalk was badly withered and pollen failed to develop. However, on the stems where the paraffin seal was removed, or where it was broken by the penetration of roots, mature diploid and tetraploid grains developed. Here also the later meiotic divisions, following the resumption of water uptake, showed no irregularities. The potted plants which were not watered for several days showed the same abnormalities, whereas after watering was resumed only normal divisions were found. The observations on these plants which were subjected to drought conditions suggest quite definitely that it is the disturbed water relations which are the cause of the abnormalities described.

Chromosome behavior.—As has been noted before (Sax, 1937), the microspores with the larger chromosome number are larger and develop more slowly. This decrease in the rate of development is apparently different in degree for the cytoplasm as compared with the chromosomes, for when the tetraploid microspore reaches the stage for cell division the chromosomes have shortened by spiralization until they are approximately half their normal length as seen in the haploid microspore (fig. 1, 6).

An increased shortening of the chromosomes in tetraploid as compared with diploid Tradescantias has been reported at meiosis by Sax and Sax (1937). The number of major coils is reported as 5.5 for the diploid form and 4.5 for the tetraploid. These

differences are attributed to the slower development of the larger cells of the tetraploid form. Comparable measurements are not given for diploid and tetraploid microspore chromosomes, but it is stated that those of the tetraploids are shorter (Anderson and Sax, 1936). In the present case the amount of shortening is much greater than previously reported. It was found that increased shortening of the chromosomes also occurred in the haploid microspore when the stems were cut and left to wilt for 24 hours. The chromosomes contracted until they were about two-thirds the length of the normal haploid microspore chromosomes (fig. 1, 2). Apparently the water deficiency itself in some manner causes increased chromosome contraction. It seems quite possible that the desiccation may cause a slowing down of cell development, thus permitting increased chromosome contraction by coiling. A similar condition occurs in microspores of colchicine treated plants, where contracted metaphase chromosomes are observed (Walker, 1938). In the microspores observed, the dehydration was not sufficient to interfere with the spindle mechanism. In fact, in no case was an inhibition of the mitotic division to form the two microspore nuclei observed. This division seems to be less easily upset than those of meiosis.

Cell division.—Besides inhibiting nuclear division, dehydration caused striking deviations in the normal rhythm of cell and nuclear division. In many cases cell division was entirely inhibited after nuclear division had occurred, resulting in bi- or quadrinucleate cells. In other cases, cell division occurred without nuclear division, occasionally in such a manner as to produce one nucleated and one enucleated cell. In some cases cytokinesis appears to be initiated but is later arrested. The division may be very unequal and a small mass is cut off from the side of the cell (fig. 9). The cell wall may constrict the nucleus, but actual bisection has not been observed (fig. 8). These abnormal cells may continue development and produce pollen grains of bizarre shapes.

Under normal conditions the meiotic cell divisions in *Tradescantia* occur by cell plate formation (Sax and Husted, 1936). Under the influence of dehydration cytokinesis may fail, resulting in a quadrinucleate cell. In many cases when the normal synchronization of nuclear and cell division was upset, cytokinesis occurred by a furrowing mechanism rather than by cell plate formation (fig. 8, 9).

Discussion.—The results of the present investigation indicate that dehydration inhibits normal spindle formation and consequently nuclear division. It does not, however, interfere with the division of the chromosomes themselves. Desiccation may also prevent cytokinesis even when nuclear division occurs, resulting in bi- and quadrinucleate cells. On the other hand, cell division by furrowing may occur without nuclear division. It seems clear as a result of this and numerous other experimental studies of mitosis and meiosis that chromosome division, nu-

clear division, and cell division are three independent, though normally synchronized processes.

It is perhaps possible that some of the diploid microspores observed in these studies may have resulted not from spindle inhibition but from desynapsis followed by an equational division of the twelve univalents. A definite relation between relative hvdration and chiasma frequency at diakinesis has been demonstrated by Straub (1937) in the case of Campanula persicifolia and by Kisch (1937) for species of Oenothera. The latter author also showed the existence of a correlation between the chiasma frequency at diakinesis and the osmotic pressure of the sap of the plant parts studied. There was a definite reduction in chiasma frequency following the cessation of watering of the potted plants and a concomitant increase in the osmotic pressure of the expressed sap of the inflorescence. However, complete desynapsis was apparently not observed in any of the plants studied. It may occur, however, as a result of the application of heat (Matsuura, 1937) or colchicine (Walker, 1938) to the microspore mother cell.

The effect of cellular dehydration on mitosis and cytokinesis has been studied in some detail with living Tradescantia cells by Wada (1936a, 1936b) using stamen hairs and by Shigenaga (1937) using young petal cells. Their findings are essentially similar to those reported here for meiosis. Desiccation of the cells with dry air or plasmolysis with hypertonic sugar solutions causes the formation of didiploid nuclei and binucleate cells. The didiploid nuclei usually result from an inhibition of spindle formation and consequently of nuclear division; the binucleate cells result from the failure of wall formation.

Milovidov (1938) has made a series of observations using fixed and stained root tips of Vicia faba from germinating seedlings allowed to dry out for varying periods. This author reports the common occurrence of fusion of two or more nuclei in a multinucleate cell to produce a polyploid nucleus. However, in the case of the bi- and quadrinucleate microspores, no such fusions were found. Polyploid gametophytes at meiosis apparently result entirely from an inhibition of nuclear division, or possibly from desynapsis, rather than from a failure of cell wall formation followed by fusion of nuclei.

The reason for the failure of spindle formation or action in dehydrated cells may possibly be explained as a result of viscosity changes. Although there are some discrepancies concerning viscosity changes at various stages in the cell cycle in the animal egg as reported by Heilbrunn (1920, 1921), Chambers (1919), and Seifriz (1920), these are to a large extent reconciled by the observations of Fry and Parks (1934). The general results indicate that

cytoplasmic viscosity is normally low at the time of spindle formation during metaphase. The work on plant cells as reported by Zimmermann (1923), Kostoff (1930a), and Kato (1933) also shows a low viscosity at metaphase. Since Kostoff worked on viscosity changes during meiosis in Nicotiana L., and Kato on meiosis in Lilium L., their results are of particular significance in connection with the present investigation. Kostoff (1930b) also studied the viscosity in plant callus tissues and suggests that the multinucleate and polyploid cells often found in such growths may be the result of the increased cytoplasmic viscosity demonstrated in these cells.

Dehydration should obviously increase the viscosity of the cytoplasm of the pollen mother cells, and this increase may interfere with normal spindle formation and action, resulting in the inhibition of nuclear division.

The observations of the disturbance of normal cell divisions at meiosis seem to indicate that cytokinesis during microsporogenesis in Tradescantia may occur by two different mechanisms. As pointed out earlier, the normal mechanism is one of cell plate formation. This occurs in connection with normal spindle formation and action, a phragmoplast apparently being involved as in mitotic cell division. When, however, the spindle mechanism is disturbed by dehydration, the production of the cell plate and consequent wall formation is interfered with and often entirely inhibited. This has been very clearly demonstrated during somatic mitosis in Tradescantia by the previously cited experiments of Wada and Shigenaga. The latter worker may well be quoted on this point: "The necessity of water for the formation of the cell membrane is shown by the fact that it is inhibited by the dehydration of the connecting spindle or phragmoplast. In the dehydrated state, even when a rudimentary cell plate is visible, it disappears, and a binucleate cell results. When the medium is replaced with water at an appropriate time, the spindle or phragmoplast swells and the new membrane is formed. When the kinoplasmic body is dehydrated in a certain limited degree, the cell membrane may be formed, but not fully. These facts must show that the cell membrane formation is also closely connected with water content in the kinoplasmic body." At meiosis such failure of the spindle action and cell wall formation results in the production of dyads or monads. However, in these cases it appears that cytokinesis may now occur by a furrowing mechanism similar to that observed in many dicotyledonous genera at meiosis. Apparently the furrowing is independent of the spindle and phragmoplast, and consequently is not necessarily coordinated with nuclear division. This same effect may be caused by temperature treatment, as can

octoploid (probably) young pollen grain, 22 days after start of dehydration.—Fig. 6, 7. Induced tetraploid microspore and young pollen grain, 19 and 23 days after sealing off cut stems with paraffin. Note greatly shortened chromosomes in microspore.—Fig. 8, 9. Abnormal tetraploid pollen grains showing unequal cell division by furrowing not coordinated with nuclear division; 23 days after start of dehydration.

readily be observed in the figures accompanying the

paper by Sax (1937).

The production of normally differentiated and apparently viable diploid and tetraploid pollen grains in Tradescantia as a result of dehydration is of considerable interest in connection with the origin of polyploidy under natural conditions. Numerous agents have been successfully used in the production of polyploid plants experimentally, but to date only one-temperature variation-has been considered as having any significance in nature. It seems possible, however, that the periodically varying water supply of plants may well be an important factor in the origin of polyploid forms under natural conditions. The experiments with potted plants demonstrate that it is possible to produce polyploid pollen grains by dehydration of the entire plant. It is of course true that desiccation has a more drastic effect on the plant as a whole than temperature variation. However, it may well be that the rather sudden and extreme temperature variations which are most effective in upsetting meiosis are not of as common occurrence under natural conditions as alternating periods of drought and moisture.

### SUMMARY

The cellular water content of *Tradescantia* buds was reduced during microsporogenesis by sealing

with paraffin the ends of cut stems kept in water or by not watering potted plants for several days. Dehydration causes the suppression of the spindle at one or both of the meiotic divisions, producing diploid and tetraploid microspores and pollen grains. The larger, probably octoploid, pollen grains occasionally observed are attributed to the inhibition of the last pre-meiotic mitosis and both meiotic divisions. Cytokinesis by cell plate formation is inhibited by dehydration, in which case division by furrowing, not coordinated with nuclear division, often occurs. Nuclear division without cell division also occurs, producing bi- and quadrinucleate cells. Chromosome length in haploid microspores from buds of cut stems allowed to wilt for twenty-four hours is reduced to two-thirds that of the length in normal haploid microspores. These abnormalities are similar to those produced by many other agents such as temperature, chemicals, and radiation and result from a disturbance of the coordination of three apparently independent though normally synchronized events: chromosome-, nuclear-, and cell-division.

It is suggested that variations of the water supply of plants may be an important factor in the production of polyploid gametes and consequently of polyploid races under natural conditions.

### INFLUENCE OF CALCIUM AND MAGNESIUM ON THE GROWTH OF CHLORELLA <sup>1</sup>

Sam F. Trelease and Millicent E. Selsam

ALTHOUGH CALCIUM is essential for the growth of all higher plants, it has long been known that Chlorella and some other green algae may be grown in culture solutions that lack this element (Molisch, 1895; Pringsheim, 1926). In this respect some of the green algae resemble bacteria and fungi, but differ from other green algae, including Spirogyra, Haematococcus, and Vaucheria, as well as from the Cyanophyceae, which, like the higher plants, require calcium for their development.

Most investigators have included calcium in the culture solution for *Chlorella* grown for physiological experiments (Warburg and Negelein, 1922, 0.0024 M; Emerson, 1929, 0.0001 M; Hopkins and Wann, 1925, 1926, 1927, usually 0.006 M; Manning, Stauffer, Duggar, and Daniels, 1938, 0.02 M). Some, however, have omitted this element (Craig and Trelease, 1937; Pratt and Trelease,

Attention is directed in the present paper to the high degree of tolerance of *Chlorella* to magnesium and to the fact that in *Chlorella* calcium does not serve as an antidote to magnesium when the latter

is present in concentrations high enough to be toxic.

Materials and methods.—Chlorella vulgaris was cultured, according to the method previously described (Craig and Trelease, 1937), in liter flasks containing 300 cc. of solution. The standard solution (similar to that of Warburg and Negelein, 1922, but with Ca omitted) contained: KNO<sub>3</sub>, 0.025 M; MgSO<sub>4</sub>, 0.020 M; KH<sub>2</sub>PO<sub>4</sub>, 0.018 M; FeSO<sub>4</sub>, 0.00001 M (with an equal concentration of potassium citrate); and stock solution of microtrophic elements, containing manganese, boron, zinc, copper, etc. (Trelease and Trelease, 1935), 14.2 cc. per liter. Experimental solutions contained, in addition, various concentrations of CaCl<sub>2</sub>, MgCl<sub>2</sub>, or MgSO<sub>4</sub>.

A mixture of 5 per cent carbon dioxide in air was bubbled continuously through the cultures, and light was supplied continuously by a water-cooled 300watt Mazda lamp about 15 cm. from the cultures. The temperature varied, but averaged about 21°C.

The cultures were seeded with approximately 35 million cells, estimated by haemacytometer counts, thus giving an initial population of about 115 cells per cmm. of culture solution. At the end of 4 days (near the middle of the grand period of growth for the control culture) the cultures were terminated,

and final populations were determined by means of a haemacytometer.

Addition of Calcium.—Excellent growth of Chlorella has been obtained in this laboratory when using a solution free from calcium (except for traces that may have been present in c.p. salts), and populations of from 7,000 to 14,000 cells per cmm. have been secured in from 3 to 5 days (Craig and Trelease, 1937; Pratt and Trelease, 1938).

The tests recorded in table 1 were made in order to determine whether the addition of CaCl<sub>2</sub>, in concentrations ranging from 0.0025 to 0.04 M, to the standard calcium-free solution would increase the growth of *Chlorella*. The data show, however, that the presence of calcium in the solution produced no significant improvement in the growth of this alga. It is evident also that *Chlorella* tolerates relatively high total salt concentrations.

Table 1. Influence of calcium chloride on the growth of Chlorella.

Culture	CaC1 <sub>2</sub>	Cell population
number	(M)	No. per cmm. % control
Control	0	12,850 100.0
1	0.0025	11,900 92.6
2	0.005	12,300 95.7

rella made significant growth (about 2.6 per cent of that of the control) in a solution containing 0.22 molar Mg (0.02 M MgSO<sub>4</sub> +0.20 M MgCl<sub>2</sub>). The data given in table 3 show that MgSO<sub>4</sub> retards growth less than MgCl<sub>2</sub>. Thus 0.42 M MgSO<sub>4</sub> reduced growth to 9.2 per cent of the control whereas 0.20 M MgCl<sub>2</sub> plus 0.02 M MgSO<sub>4</sub> reduced it to 2.5 per cent.<sup>2</sup> The difference may be due to the lower osmotic value of the MgSO<sub>4</sub>.

Table 3. Comparison of the toxicity of magnesium chloride and magnesium sulphate to Chlorella.

	Cell population				
Solution	No. per cmm.	% control			
Control	31,767	100.0			
.02 M MgSO <sub>4</sub>	810	2.5			
.20 M MgCl <sub>2</sub> ) .42 M MgSO <sub>4</sub>	2,930	9.2			

It is evident that Chlorella exhibits a remarkable tolerance to high concentrations of magnesium, even in the absence of calcium. In contrast, wheat seedlings are seriously injured by a concentration as low as 0.0025 M MgCl<sub>2</sub> if the Mg/Ca ratio exceeds 2/1 (Trelease and Trelease, 1931), and higher plants exhibit pronounced pathological symptoms when relatively low Mg concentrations are used in culture solutions that contain less than equivalent concentrations of Ca (Tottingham, 1914; Shive, 1915; Garner, McMurtrey, Bowling, and Moss, 1930).

<sup>2</sup> Other tests have shown that when Chlorella is cultured in a north window (and without additional CO<sub>2</sub>) the rate of growth in a solution containing 0.42 M MgSO<sub>4</sub> may be approximately 50 per cent of that in the control solution. Under these conditions the alga grows very slowly—the cell population after one month being only about 1,000 cells per cmm. in the control solution.

The Chlorella cells grown in 0.20 M MgCl<sub>2</sub> or 0.42 M MgSO<sub>4</sub> showed no decrease in protoplasmic contents. This is in marked contrast to the loss of all stainable cell contents observed by Bamford (1931) in roots of wheat and corn grown in solutions containing from 0.00125 to 0.02 M MgCl<sub>2</sub> and little or no Ca.

The tolerance of *Chlorella* to magnesium was used in this laboratory a number of years ago as the basis for a method of destroying protozoa in a culture that had been neglected for several months. A sufficient quantity of a strong MgSO<sub>4</sub> solution was added to give a concentration of 0.45 M. After from 12 to 24 hours, transfers made by centrifuging and decanting produced stock cultures free from protozoa.

Absence of Calcium-Magnesium antagonism.—In view of the pronounced action of calcium in counteracting the toxicity of magnesium to higher plants, one might expect that calcium would reduce the toxicity of very high concentrations of magnesium to Chlorella. Table 4, however, shows that when enough MgCl<sub>2</sub> was added to the culture solution to depress the growth of Chlorella, the addition of CaCl<sub>2</sub> had no antagonistic action in diminishing the depression of growth brought about by the MgCl<sub>2</sub>.

The results obtained with Chlorella thus resemble those of Mann (1932), who found that CaCl<sub>2</sub> did not antagonize the poisoning of Aspergillus niger by very high concentrations of MgCl<sub>2</sub>.

The colorimeter tests recorded in table 4 show that additional magnesium reduced the cell population much more than it diminished the greenness of the cultures.

General conclusion.—The higher plants (wheat, corn, tobacco, etc.), which require calcium for their development, are readily poisoned by low concentrations of magnesium in the absence of cal-

cium. But the lower plants (Chlorella, Aspergillus, etc.) that do not utilize calcium in their growth tolerate very high concentrations of magnesium; and in these lower plants calcium is not an antidote for magnesium, as it is in the higher plants.

### SUMMARY

The growth of Chlorella vulgaris was not increased by the addition of calcium chloride to the culture solution. In the absence of calcium this alga

tolerated high concentrations of magnesium salts, making considerable growth in a concentration as high as 0.42 molar magnesium sulphate. When enough magnesium was added to the culture solution to depress the growth of Chlorella, the addition of calcium did not diminish the toxicity of the magne-

### THE PERENNIAL MEXICAN NAMAS 1

### C. Leo Hitchcock

Since the writer's treatment of the genus Nama in 1933 several botanists have collected interesting series of plants of the genus from the Texas-Mexican border and from the central Mexican plateau. An examination of this material has helped to clarify the status of some of the poorly known and seldom collected Mexican species.

One of the least well-understood species (so far as I am concerned, at least) is N. stenophyllum Gray. During the summer of 1938 Dr. I. M. Johnston collected and made careful field notes on several plants which are allied to that species, but which apparently are not all conspecific with it. Dr. Johnston has sent me this material together with the rest of the Mexican material at the Gray Herbarium, and careful study of these collections has con-

<sup>1</sup> Received for publication March 4, 1939.

This paper may be considered a supplement to the papers in the American Journal of Botany 20: 415-430, 518-534, 1933, in which the entire genus was reviewed, and to which frequent reference will be made in this article without recourse to citation other than pagination.

vinced me that several changes should be made in the classification which I proposed in 1933, especially as concerns the perennial species of the section Eunama.

In addition to the material from the Gray Herbarium I have borrowed collections from the United States National Herbarium (US), Texas Agricultural College, and University of California (C). My gratitude to the curators of these herbaria is hereby acknowledged.

KEY TO THE PERENNIAL SPECIES OF EUNAMA2

Corollas less than 15 mm. long.

Leaves 1.5-8 cm. long, long-petiolate; ovary 4-12-

<sup>2</sup> This key includes some plants, such as N. stenophyllum, N. canescens, and N. Havardii, which could probably be described more accurately as annuals, but which are much longer-lived than such annuals as N. demissum, N. hispidum, N. dichotomum, N. Coulteri, etc., which were treated as the annual species of Eunama.

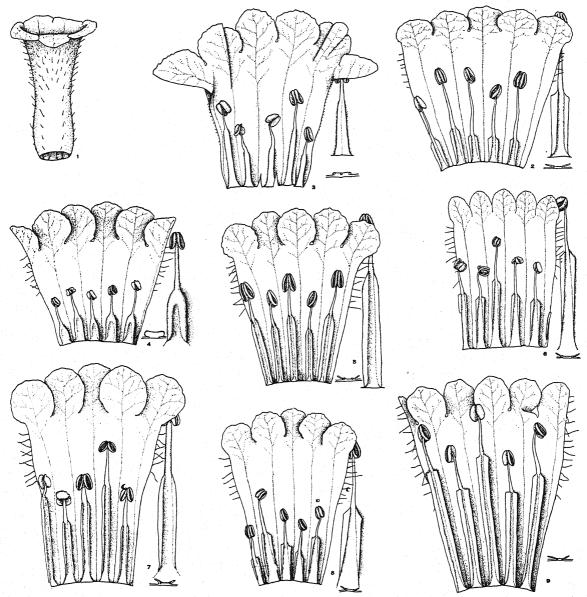

Fig. 1-9.—Fig. 1. Corolla of N. propinquum, unopened.  $\times 5$ .—Fig. 2-9. Corollas of several species of Nama opened to show attachment of stamens. All  $\times 5$ . In all except figure 9 one stamen also is shown enlarged  $\times 10$ , and in each instance a cross-section of the adnate portion of one stamen is shown at the lower right-hand corner of the corolla.—Fig. 2. N. propinquum, drawn from type.—Fig. 3. N. hispidum.—Fig. 4. N. canescens, drawn from type.—Fig. 5. N. stenophyllum, drawn from type.—Fig. 6. N. carnosum, drawn from type.—Fig. 7. N. stenophyllum, drawn from type of N. Purpusii.—Fig. 8. N. flavescens, drawn from type.—Fig. 9. N. Johnstonii, drawn from type.

Leaves seldom as much as 4 cm. long, but if that long, sessile or short-petiolate; ovary with more than 12 seeds (except in N. serpylloides and possibly in N. propinquum).

Leaves mostly opposite; plants diffusely branched, slender-stemmed, hirtellous; corollas 5-6 mm. long. Pedicels ca. 10 mm. long; plants not velvety.

N. serpylloides

Pedicels less than 5 mm. long; plants velvety.

N. serpylloides var. velutinum Leaves prevailingly alternate; plants otherwise not as in N. serpylloides.

Filaments inserted at the same level ca. ½ mm. from base of corolla, widened at point of insertion, but the adnate portion not wing-margined.

Flowers borne on long slender pedicels (or peduncles) 4-12 mm. long; free portion of filaments definitely longer than adnate portion.

Petioles broadly wing-margined, those of larger leaves at least 1 mm. broad, often decurrent on stem; pubescence villous-hirsute to hirsute.

Blades cordate or truncate at base, as broad as long; pedicels 1-4 mm. long; styles not connate; plants from woody crowns.

N. propinquum Blades acute or obtuse at base, longer than broad; pedicels mostly over 4 mm. long; styles usually somewhat connate for short distance; plants herbaceous below.

N. biflorum

Free portion of filaments definitely much longer than adnate portion; leaves mostly over 4 mm. broad (except in N. Palmeri var. argenteum).

N. Palmeri var. argenteum Free portion of filaments subequal to, or shorter than, adnate portion; leaves less than 4 mm. broad, except in N. Havardii.

Plants sericeous-villous; leaves 2-4 cm. long, 0.4-1.5 cm. broad......N. Havardii Plants with harsher pubescence than in N. Havardii (i.e., not villous); leaves 0.1-0.3 (or very rarely as much as 0.4) cm. broad.

Plants fairly shrubby at base, with irregularly furrowed bark, the larger branches 1 cm. in diameter or thicker; plants grayish-green, densely and uniformly strigose-hirsute-hispid, hairs mostly ca. 1 mm. long; stamens unequally inserted, filaments adnate % the length of the corolla (or more), free portion 1-1.5 mm. long, adnate portion with narrow winged margin.

N. Johnstonii
Plants not shrubby, or if so, not otherwise as above, either yellowish green

and sparsely strigose, or stems with dense fine pubescence in addition to sparse strigosity.

Stems sparsely strigose (the hairs nearly 1 mm. long, the bases papillosepustulose) and very densely and finely pubescent (these hairs ca. 0.2 mm. long); free portion of filaments 1-2 mm. long, the adnate portion 2-4 mm. long, but the free-margined edges not extending all the way to the base Stems uniformly pubescent, or at least without fine pubescence as short as 0.2 mm. in length; filaments (except in N. flavescens) not as in N. carnosum, the free-margined edges of adnate portion usually extending practically to base of corolla.

Plants slightly shrubby at base, with roughened bark on main branches, densely granular-glandular all over; leaves yellowish-green, sparsely strigose; sepals 4-6 mm. long; corollas exserted 3-4 mm.

### EMENDED TREATMENT OF SPECIES AND VARIETIES

N. serpylloides var. velutinum C. L. Hitchc. var. nov.—Habit of N. serpylloides, but entire plant densely hirtellous-velutinous, hence grayish-green; branches thicker than in the species; leaves all opposite, obovate or obovate-oblanceolate, 5-9 mm. long, 2-4 mm. broad, thick and fleshy, revolute; flowers sessile or on pedicels 1-4 mm. long; sepals linear-oblanceolate, 2-3 mm. long, rounded; corollas 4-6 mm. long, the tube yellowish, lobes pinkish; filaments subequally inserted ca. 1 mm. above base of corolla, the bases widened slightly and very narrowly wing-margined at point of insertion, the wings not extending to the base of the corolla, the free filaments 1-1.5 mm. long; styles ca. 1.5 mm. long; capsules 10-20-seeded; seeds as in the species. (Planta habitu N. serpylloidei similis sed velutina; pedicellis 1-4 mm. longis; foliis crassis, 5-9 mm. longis, 2-4 mm. latis.)

Type; one mile south of Hermanas, on road from Piedras Negras south to Monclova, Coahuila, Mexico, on dry heavy alkaline soil on terrace near saltmarsh, Aug. 22-24, 1938, I. M. Johnston 7063 (Gray Herbarium). Other material seen; 2 miles west of Cuatro Cienegas, road from Monclova westward to beyond Cuatro Cienegas, Coahuila, Mexico, Aug. 25, 1938, Johnston 7126 (G).

That the plants represented in these two collections are closely related to N. serpylloides, there can be no doubt, the species as a whole being the only Nama characterized by opposite leaves; however, although Johnston noted that his plants were collected on very alkaline soil, I believe that the differences between them and the species, proper, are not entirely due to ecological conditions.

N. propinguum Morton and Hitchcock spec. nov.—A gravish, densely hirsute perennial nearly a foot high, from a definitely woody crown; leaves silvery-gray, cordate-deltoid, the larger blades about 2 cm. long and as broad, the veins very prominent, the petioles about 1 cm. long, narrowly wing-margined, the margins sometimes somewhat decurrent on the stems; flowers borne singly or in pairs on slender peduncles and pedicels 5-10 mm. long, the pedicels alone usually 1-4 mm. long; sepals linear, ca. 5 mm. long; corollas narrowly tubular-obconic, 8-9 mm. long, the throat pubescent on the exterior; stamens unequal, slightly over half as long as corolla-tube, filaments unequally inserted 1-2 mm. from base of corolla, the adnate portion flared just below upper limit of adnation, then narrowed to base, the margins free; styles 3-4 mm. long, not connate at base; ovaries with more than 20 ovules, but mature seeds not seen.

Planta perennans, suffrutescens, 15-25 cm. alta, cinereo-hirsuta; foliis cordato-triangularibus, usque ad 2 cm. longis et 2 cm. latis, venis prominentibus; petiolis ca. 1 cm. longis, alatis, subdecurrentibus; floribus in cincinnis axillaribus, 1-2-floris; pedicellis 1-4 mm. longis; sepalis ca. 5 mm. longis, linearibus; corollis 8-9 mm. longis; staminibus per 1-2 mm. cum corolla coalitis, alato-dilatatis; stylis non connatis; ovulis numerosis, seminibus mihi ignotis.

Type; Rancho Agua Dulce, dry arroyo on the slopes of the Sierra de San Manuel, Musquiz, Coahuila, Mexico, June 28, 1936, Wynd & Mueller 333 (U. S. Nat. Herb. No. 1639772). Isotype at Gray Herbarium.

The nearest relative of this species is undoubtedly *N. biflorum* Gray, a species which differs from *N. propinguum* as follows:

N. biflorum

veins of leaves only grayish; pubescence villoushirsute;

leaves ovate to spatulate; petioles broadly winged, always decurrent on stems;

pedicels usually over 4 mm. long; styles usually slightly connate;

annual or biennial, crown not woody.

N. propinguum

whole plant silvery-gray; pubescence hirsute, much harsher than in biflorum; leaves cordate-deltoid; petioles not so broadly winged as in biflorum, scarcely decurrent on stems;

pedicels usually less than 4 mm. long; styles not connate;

perennial, the crown quite woody.

Mr. C. V. Morton, of the National Herbarium, tentatively identified this Nama as a new species, and it is with his permission that I use his herba-

rium name and publish the species under our joint authorship.

N. xylopodum (Woot. & Standl.) C. L. Hitche. Amer. Jour. Bot. 20: 428. 1933.—My description of this species should be emended to note that the leaves are sometimes as much as 15 mm. long and 7 mm. broad.

N. spathulatum T. S. Brandegee, Zoë 5: 253. 1908.—Upon reexamination of the material of N. spathulatum and N. Palmeri, I am more inclined than ever to believe that those two species are not specifically distinct. However, the differences I pointed out (p. 425) still stand in the light of present collections, although the types of the two species—namely, Purpus 2584, from Cerro de Paxtla, Puebla, and Palmer 856, 25 miles southwest of Monclova, Coahuila—are more than superficially alike.

N. Johnstonii C. L. Hitchc. spec. nov.—A gravish-green perennial from a woody base, the plants rounded shrubs 20-35 cm. tall, 15-30 cm. in diameter; basal branches as much as 1.5 cm. thick, decidedly woody, with thick furrowed bark, devoid of leaves for 5-15 cm.; whole plant somewhat mealyglandular and strigose-hirsute-hispid, the hairs of older leaves with papilliform bases, mostly ca. 1 mm. long; leaves linear, 10-25 mm. long, 1-2 mm. broad, revolute; flowers 1-several per peduncle, mostly at ends of short herbaceous branches on pedicels 1-5 mm. long; sepals linear, ca. 1 cm. long, 0.5-0.75 mm. broad; "corollas white, 3 purple lines on each lobe," 10-12 mm. long, hirsutulous on the exterior; filaments unequally inserted, adnate for ca. 2/3 length of corolla-tube (or for greater distance), free portion 1-1.5 mm. long, adnate portion widened and with narrow winged margins for entire length; styles distinct to base, 4-5 mm. long; seeds numerous (50-100?), light brown, ca. 0.3 mm. long, very irregularly many-sided, finely alveolate, the edges somewhat granular.

Planta suffrutescens, perennans, 20–35 cm. alta, 15–30 cm. lata; caulibus usque ad 1.5 cm. crassis, lignescentibus; plantis glandularibus, strigosis, hirsuto-hispidis; foliis linearibus, 10–25 mm. longis, 1–2 mm. latis, revolutis; cincinnis 1–4-floris; pedicellis 1–5 cm. longis; sepalis linearibus, ca. 10 mm. longis, 0.5–0.75 mm. latis; corollis 10–12 mm. longis; staminibus per 3–5 mm. cum corolla coalitis, partibus adnatis alato-dilatatis; stylis 4–5 mm. longis, non connatis; seminibus 50–100, brunneis, ca. 0.3 mm. longis, minute alveolatis et granularibus.

Type: 6 miles west of Viesca, Coahuila, Mexico, on limestone cliffs in steep canyon, Sept. 17, 1938, I. M. Johnston 7740 (Gray Herbarium). Other material seen: State of Chihuahua (probably from the great canyon near Chihuahua City, according to I. M. Johnston), Pringle 120 (G, US).

This species, as represented by the Pringle collection, was referred to D. stenophyllum by me and by Macbride. However, Dr. Johnston pointed out the similarity of his collection to that of Pringle and called attention to the shrubby nature of the plant and to the fact that it is found on limestone

cliffs, whereas N. stenophyllum is found chiefly on

gypsum soil.

Since there is good reason for considering this shrubby plant to be a distinct species (for comparison with N. stenophyllum see under the latter species), I have restudied the other forms which I included under N. stenophyllum in my former paper, and now believe that it would be more consistent to recognize N. carnosum and N. flavescens as distinct also, the four species (N. carnosum, flavescens, stenophyllum, and Johnstonii) undoubtedly being of common origin and rather closely related.

N. carnosum (Woot.) C. L. Hitchc. comb. nov.— Conanthus carnosus Woot., Bull. Torr. Bot. Club 25: 262. 1898. Andropus carnosus (Woot.) Brand, Fedde Rep. Spec. Nov. 10: 281. 1911, and Pflanzenr. 4<sup>251</sup>: 163, fig. 32. 1913. N. stenophyllum var. egenum Macbride, Contr. Gray Herb. 49: 44. 1917; Hitchc., l.c. 425.

Unfortunately the only two collections of this plant that seemingly are extant (namely Havard 15, from bluffs of Delaware Creek east of Guadalupe Mts., Texas, the type of Macbride's variety egenum, and Wooton 164, from White Sands, Dona Ana Co., New Mexico, type collection of N. carnosum) are both past anthesis; therefore all observations concerning the flowers have perforce been made from a few fragmentary undersized blossoms. As I pointed out previously, the filament bases are not bifid, although they seem to be because of the fact that the free-margined adnate filament bases do not extend to the base of the corolla. My previous illustration (l.c. plate 27, fig. 17) for N. stenophyllum was made from Wooton 164. After studying the 1938 collections made by Johnston, it is clear that the above-mentioned figure, although approximately correct for N. carnosum, does not accurately represent the stamen structure in N. stenophyllum, proper, but that the figure for N. Purpusii (fig. 32) more nearly represents their true nature. I have accordingly redrawn the corollas of N. stenophyllum and its allies for purposes of comparison.

Since N. stenophyllum is apparently never woody at base, whereas N. carnosum is woody, I believe that the latter can justifiably be maintained as a species characterized by its woody crown, long branches that are simple below, and by the peculiar pubescence described in the key. In all these respects it more closely resembles N. flavescens (N. stenophyllum var. flavescens) than it does N. stenophyllum itself.

It is to be hoped that collectors will make a special attempt to collect this species, as it surely must have been seen in the field by other botanists, but might easily be passed up as unsatisfactory for collecting due to its dark color and "dried-up" appearance.

N. flavescens T. S. Brandegee, Zoë 5: 254. 1908, Brand, l.c. 158. N. stenophyllum var. flavescens (Brandegee) C. L. Hitchc. l.c. 425.—Since the stamen bases of those plants are seemingly more like

those of *N. carnosum* than like those of *N. stenophyllum*, and because the plants are apparently somewhat woody at base, I believe that they, too, can reasonably be maintained as a species, rather than as a variety of *stenophyllum*, although additional material might show that such is not the case.

N. stenophyllum Gray ex Hemsl. Biol. Cent.-Am. Bot. 2: 361. 1882; Brand, l.c. 145; Hitchcock, l.c. 425. Conanthus stenophyllus (Gray) Heller, Cat. N. Am. Pl. 6. 1898. Marilaunidium stenophyllum (Gray) Kuntze, Rev. Gen. Pl. 2: 434. 1891. N. Purpusii T. S. Brandegee, Univ. Cal. Pub. Bot. 4: 186. 1911; Brand, l.c. 159; Hitchcock, l.c. 426.

After comparing the types of N. Purpusii and N. stenophyllum with the material collected last summer by Johnston, I can see that I misinterpreted the nature of the filaments of the latter and that they are the same as those of N. Purpusii. Therefore the only real difference which I supposed existed between these two "species" does not really exist at all. Table 1 shows why I consider these two to be conspecific and also shows the difference between N. stenophyllum and its closest allies.

N. canescens C. L. Hitchc. spec. nov.—A decumbent to ascending rounded annual or biennial 5-20 cm. tall, grayish, appressed-hispid throughout, the hairs mostly ca. 1 mm. long, some slightly shorter and more slender, pubescence also present on stems; stems several from base, freely branched, very leafy; leaves linear, 10-25 mm. long, 1-1.25 mm. broad (nearly terete?); flowers mostly in terminal and axillary few-flowered bracteate cymes; pedicels 1-2 mm. long; sepals free to base, linear, 4-6 mm. long at anthesis, to 10 mm. long in fruit; corolla pink, ca. 8 mm. long; stamens subequally inserted 1-2 mm. from base of corolla, the longer ones ca. ½ as long as corolla, free portion of filaments ca. equal to adnate bases or slightly longer, the adnate portions broadened to nearly 3 times the width of the free filament, the edges thickened and scarcely free; styles not connate; seeds brown, irregularly many-sided, alveolate and somewhat granular, ca. 0.4 mm. long.

Planta habitu N. stenophyllo similis sed hispida; foliis linearibus, 10-25 mm. longis, 1-1.25 mm. latis; corollis ca. 8 mm. longis; staminibus per 1-2 mm. cum corolla coalitis, partibus liberis 1-2 mm. longis, partibus adnatis dilatatis sed marginibus non alatis; seminibus brunneis, ca. 0.4 mm. longis.

Type: 38 miles south of Matehuala, San Luis Potosi, Mexico, on disturbed soil of gypsum plain, Sept. 10-11, 1938, I. M. Johnston 7510 (Gray Herbarium). Other material seen: 2 miles south of Cedral, San Luis Potosi, on gypsum plain, Sept. 11-12, 1938, Johnston 7584 (G).

This is a rather puzzling species, resembling N. hispidum in some respects and N. stenophyllum in others, but it is probable that it is much more closely related to the latter than to the former, as shown in table 2 below.

TABLE 1.

stenophyllum	Purpusii	Johnstonii	flavescens	carnosum
Sturdy annuals or biennials, bases not woody; stems very leafy, fascicles and reduced branches in most axils.	Same.	Woody-based perennial; branches as much as $1\frac{1}{2}$ cm. thick, with grayish bark, irregularly branched but without the numerous short branches of stenophyllum.	Shrubby-based perennial, bark thick, branches many, simple, without fascicles and reduced branches in the axils of the larger leaves.	Base woody, rough barked, several long branches from base, these branched only near tips
Plant grayish, hispid- strigose-hirsute throughout, longer hairs 1-1.5 mm. long, often with shorter hairs also present, all hairs straight and fairly stiff, not papillose or glandular.	Same.	Grayish-green, strigose hirsute-hispid, hairs on older leaves with papil- liform bases; hairs mostly ca. 1 mm. long; plant somewhat mealy- glandular throughout.	Yellow-green, very densely granular-glan- dular all over, sparsely strigose, the hairs less than 1 mm. long, some- what papilliform.	Sparsely strigose, th hairs ca. 0.75 mm. long papilliform-pustulose stems densely pubescen also, with short hairs no over 0.25 mm. long.
Leaves revolute, linear, 10-50 cm. long, 1-3 mm. broad.	Same.	Revolute, linear, 10-25 mm. long, 1-2 mm. broad.		Linear, revolute, 10-3 mm. long, 1-1.5 mm broad.
Pedicels 1-3 mm. long.	Same.	1-5 mm. long.	1-3 mm. long.	1-2 mm. long.
Sepals 7-9 mm. long, linear-spatulate.	8–10 mm. long.	Linear, ca. 10 mm. long.	Linear, 4-6 mm. long.	Linear, ca. 7 mm. long.
Corolla 7.5-9 mm. long, not exserted.	8–10	10-12 mm. long, often exserted.	8-9 mm. long, exserted.	Ca. 7 mm. long?
Stamens unequally inserted, adnate portion 2-5 mm. long, free portion 1/2 as long to as long as adnate, free-margined portion.	Same.	Much same as steno-phyllum but adnate nearly % length of corolla.	Unequally inserted, adnate portion 1-3 mm. long, free portion ca. equal to adnate portion, adnate portion, adnate portion expanded, with narrow free margins running not quite to base of corolla.	Much same as in flaves cens.
Seeds brownish, 0.3-0.5 mm. long, very irregularly compressed, finely alveolate, the edges somewhat granular.	Same.	Same.	Same.	Same.

TABLE 2.

N. stenophyllum	N. canescens	N. hispidum
Vigorous long-lived annual or biennial.	Same as stenophyllum.	Short-lived annual.
Leaves linear, 1-1.25 mm. broad.	Same.	Variable, but mostly over 1.5 mm. broad.
Strigose-hispid-hirsute.	Hispid.	Hispid to hirsute.
Sepals lanceolate, 7-10 mm. long.	Linear, 4-10 mm. long.	Linear or linear-lanceolate, 4-7 mm. long.
Corollas 8-10 mm. long.	Ca. 8 mm. long.	8-15 mm. long.
nate 2-5 mm.; free filaments 1/3 as	adnate for 1-2 mm.; free filaments equal to or longer than adnate por-	Ca. ½ as long as corolla, adnate 1-4 mm., free portion longer than adnate portion, the adnate bases neither winged nor free-margined.
Seeds brown, many-sided and flat- tened, somewhat granular.	Same.	Yellow, ovoid, smooth but alveolate- reticulate.

### NOTES ON THE ANNUAL SPECIES

Nama hispidum Gray, Proc. Am. Acad. 5: 339. 1861.—Two of Dr. Johnston's collections—namely, Johnston 7406, Hacienda de Sierra Hermosa, Zacatecas, and Johnston 7633, from 6 miles north of La Ventura, Coahuila—are unusual in that the plants are prostrate and very narrow-leaved. However, the pubescence, flowers, and seeds are those of N. hispidum, and I hesitate to assign them any distinctive status, nomenclaturally, in such a perplexing species. Both series of plants were growing on gypsum soil.

Nama Coulteri var. Pringlei (Rob. & Greenm.) C. L. Hitche. l.c. 526.—A further difference between this plant and N. Coulteri is that the stems and calyces are densely gray hirsute, the hairs being 1 mm. long or longer. I believe that it would probably be wisest to accord the entity specific status as

was done by Robinson and Greenman, Proc. Am. Acad. 32: 38, 1896.

### SUMMARY

The perennial Mexican species of Eunama have been restudied and based on recent collections of Mexican material; 3 new species, N. Johnstonii, N. canescens, and N. propinquum, and one new variety, N. serpylloides var. velutinum, are described.

It is now proposed to maintain N. carnosum and N. flavescens as valid species; N. Purpusii is reduced to synonymy under N. stenophyllum; and it is suggested that N. Pringlei might more consistently be treated as a species than as a variety of N. Coulteri.

### RELATION OF STOMATAL OPENING TO WATER SOAKING OF TOBACCO LEAVES <sup>1</sup>

Stephen Diachun and W. D. Valleau

SINCE THE theory has been advanced that water soaking of leaves is a necessary prerequisite to the development of "epidemic" wildfire and late-season blackfire of tobacco (Clayton, 1936, 1937), further information was sought concerning the factors which modify the susceptibility of leaves to water soaking. Clayton (1936) reported that leaf maturity, height of topping, presence of leaf injuries, fertilization, and surface of leaf exposed modified the susceptibility of tobacco leaves to water soaking, but did not offer any explanation as to how these factors affected susceptibility. In the process of soaking a leaf with a strong spray of water, the water presumably enters the intercellular spaces by way of stomata or leaf injuries. The suggestion thus occurred that the condition of the stomata might have some bearing on the susceptibility of leaves to water soaking.

In the present studies it was found that leaves water soaked very slowly (1) when light intensity was low late in the afternoon, (2) when leaves were shaded, (3) when leaves were wilted or beginning to wilt, or at any other times when the stomata might be expected to be closing or closed. It is the purpose of this paper to report studies which indicate that the susceptibility of tobacco leaves to water soaking is determined largely by the degree of opening and condition of the stomata.

Methods.—Leaves were water soaked by directing a stream of water from a glass tube against the

<sup>1</sup> Received for publication February 10, 1939. The investigation reported in this paper is in connection with a project of the Kentucky Agricultural Experiment Station and is published by permission of the Director. lower surface. All tests were made on the lower surface, because storm injury in the field is more prevalent on leaves whose lower surfaces are exposed after the leaves are turned over by wind. To produce the stream of water, a simple apparatus was used: a glass capillary tube 2 cm. long with a bore of .75 mm. was connected by means of a heavy walled rubber tube to a ½-inch iron pipe fitted with a pressure gage and valve; the pipe was connected to the water line by a garden hose. Water pressure could be kept fairly uniform by means of the gauge and valve. Susceptible leaves could be water soaked easily without mechanical injury when the nozzle was held 30 cm. from the leaf surface with a pressure of  $7\frac{1}{2}$  lbs. per square inch.

The method used to determine the susceptibility of a leaf to water soaking was as follows: a flat board was placed against the upper surface of the leaf; a flat piece of sheet metal with a hole 4 cm. square in the center of it was then placed over the lower surface of the leaf; a stream of water was directed at the leaf through this opening with the nozzle 30 cm. away; the stream of water was moved across the exposed leaf from side to side as rapidly as the tissues became soaked until the whole area was soaked. The time required to water soak the 16 cm.2 area was recorded to the nearest 5 seconds, if less than a minute was required, or to the nearest quarter minute at the longer periods. Because a difference was observed in the susceptibility of base and tip of some leaves, three areas of each leaf were water soaked: base, middle, and tip.

The alcohol method of Lloyd (1908) was used in examining the stomata. To facilitate comparison of

the condition of the stomata at different times, an index of the degree of stomatal opening was used; this index, expressed as K, is the ratio of the average actual width to the average potential length of the opening of 20 measured stomata.

These studies were confined to White Burley tobacco grown in the greenhouse in half-gallon pots or in the ground bench. A coat of whitewash on the glass of the house reduced the intensity of sunlight.

Effect of time of day and intensity of sunlight on susceptibility to water soaking.—Repeated observations and tests showed that leaves water soaked much more slowly late in the afternoon than in the forenoon or early afternoon. At 9 a.m., April 13, 1938, the time required to water soak 16 cm.<sup>2</sup> of each of eleven leaves on a plant in the ground bench was determined. Other 16 cm.<sup>2</sup> areas of the same leaves were water soaked at 4 p.m. the same day and at 9 a.m. the next day. On both mornings the leaves water soaked in about 1/6 the time required late in the afternoon. The middle leaves water soaked most readily, and the tip leaves least readily. This was the case throughout these studies.

Hourly records were then made on the degree of opening of stomata and the time required to water soak 16 cm.<sup>2</sup> over a 24-hour period beginning at 8 a.m., May 5, 1938. The test was made on middle leaves of mature plants in bloom in the ground bench, and on middle leaves of small potted plants

with 7 to 10 leaves per plant. The soil was kept moist throughout the test so that there was no wilting during the hot part of the afternoon.

From 8 a.m. until 4 p.m. the leaves water soaked readily, and most of the stomata were open. At 5 p.m. the leaves water soaked more slowly, and the stomata were beginning to close. During the night the leaves water soaked very slowly, and most of the stomata were closed or nearly so. At 6 a.m. some of the stomata were opening, and the leaves water soaked more readily. At 7 a.m. most of the stomata were wide open, and the leaves water soaked rapidly. This experiment was repeated on September 10, 1938. The hourly observations presented in table 1 show that leaves water soaked easily during the hours of daylight when most of the stomata were open. At night when most of the stomata were nearly closed, leaves water soaked much more slowly.

Since the coming of nightfall and darkness tended to induce closure of stomata and an accompanying increased resistance to water soaking, it was thought that artificial darkness might have a similar effect. Therefore, on August 2, 1938, at 9:45 a.m., the susceptibility to water soaking and the degree of stomatal opening was determined for a leaf of a potted plant (15 leaves). The plant was then put into a dark room. At 15-minute intervals for an hour, 20 stomata were measured and the time required to water soak 16 cm. 2 determined. At the end

Table 1. Effect of time of day on susceptibility of tobacco leaves to water soaking, and on the degree of opening of stomata.

of the hour the plant was returned to the green-house. For another hour stomata were measured and the time required to water soak 16 cm.<sup>2</sup> determined at 15-minute intervals. Table 2 shows that the stomata were closed 15 minutes after being placed in the dark and remained closed until the plant was brought into the greenhouse, when they began to open. The susceptibility to water soaking was closely correlated with the degree of stomatal opening. This experiment was repeated several times with similar results.

Table 2. Relation of light and artificial darkness to opening and closing of stomata and susceptibility to water soaking.

<sup>a</sup> Plant removed to dark room at 9:46.

b Plant removed from dark room at 10:46.

Shaded parts of leaves did not water soak as readily as those parts exposed to direct sunlight, as is shown in the following experiment. A leaf of a plant in the ground bench was partly shielded from light by a paper mask for one hour. The mask was then removed and the entire leaf sprayed from the

lower side. Only the part exposed to light became water soaked (fig. 1). The stomata on the exposed part of the leaf were open, K being .34, while those on the masked part were nearly closed, K being .06. This experiment was repeated several times with the same result.

EFFECT OF LOW LIGHT INTENSITY DURING THE DAY ON WATER SOAKING AND STOMATAL OPENING. On August 11, 1938, hourly observations were made on the degree of opening of stomata and the ease of water soaking of leaves. The morning was partly cloudy; stomata were open and leaves water soaked easily. About noon it began to rain and remained cloudy and dark all afternoon. At 1 p.m. stomata were partly closed, and leaves water soaked about nine times more slowly than in the morning. The stomata were partly closed all afternoon, and leaves water soaked slowly. With nightfall stomata did not close as they had been observed to do on previous nights but remained partly open all night. Leaves water soaked more rapidly than on previous nights when stomata had been nearly closed (table 3). After midnight a full moon was shining. Whether this had any effect on keeping stomata open is not known.

Loftfield (1921) observed that in alfalfa a night opening of stomata occurred when some factor such as water shortage caused stomata to close in the afternoon. Presumably tobacco leaves behave in a similar manner. A partial closure of stomata in the afternoon caused by low light intensity seemed to induce a partial opening throughout the night.

RESISTANCE OF WILTING LEAVES TO WATER SOAK-ING.—Leaves beginning to wilt usually could not be water soaked. On June 20, 1938, a plant in the ground bench began to wilt at 11 a.m. Several leaves were drooping at the tip and margins. When the lower surface of one of these leaves was sprayed in the usual manner, the central portion of the leaf water soaked rapidly, but the tip and margins only very slowly. The stomata in the center of the leaf were open, K being .39; those on the margin of the leaf were nearly closed, K being .10. However, sometimes even wilting leaves water soaked rapidly over the entire surface. At such times the stomata were found to be uniformly open.

RELATION OF STOMATAL OPENING TO WATER SOAK-ING IN OLD LEAVES AND IN YOUNG TIP LEAVES.—Clayton (1936) reported that basal leaves water soaked more readily than young tip leaves on the same plant. The writers found that the middle leaves of Burley tobacco water soaked more rapidly than the low, more mature leaves (table 4). In view of the fact that the degree of stomatal opening was seen to be a factor in determining the ease of water soaking and that Loftfield (1921) had reported stomata in old yellow leaves of alfalfa to be permanently closed, the stomata in old, basal, yellowing leaves were examined. It was found that the majority of the stomata in such leaves were always closed or very nearly so. Furthermore, some of them

appeared to be non-functional, with degenerating guard cells (fig. 2).

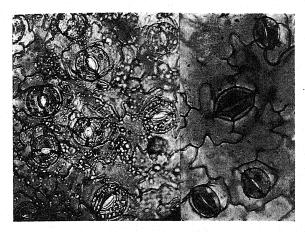

Fig. 2. Left. Normal stomata from middle leaf of a Burley plant. Right. Stomata from basal yellowing leaf of a Burley plant. Most of the stomata are nearly closed; some of the guard cells are degenerating. Both taken from leaves at 11 a.m. of a sunny day.

The ripening leaves of a low-topped plant have small, yellow patches on a green background. These yellow areas water soaked slowly even when the green portions of the leaf water soaked rapidly. In the green regions the stomata were large and still functional, most of them being open during the day. The stomata in the yellow areas, however, were closed, for the most part, and many of them were structually deformed, resembling those on old, yellow, basal leaves of untopped plants.

Young tip leaves consistently water soaked much more slowly than more mature middle leaves (table 4). This is in accord with Clayton's results. Microscopic examination showed stomata on tip leaves to be less fully developed than those on middle leaves. This is in agreement with the observation of Clinton and McCormick (1922). These workers reported that they were able to produce abundant wildfire infections on uninjured tissues of mature or nearly mature leaves inoculated by spraying, when environmental conditions were favorable for the opening of stomata. However, when immature leaves were sprayed, infections rarely occurred. This "indicates that the entrance takes place through the stomates which in these leaves are not so fully developed or liable to be open." Furthermore, the tips

of such young leaves could be water soaked easily when the bases of the same leaves could not be. Since the tip of a leaf is believed to become mature before the base (Avery, 1933), it was felt that the stomata might be more fully developed at the tip. Examination of stomata at the tip and base of young leaves shows this to be the case.

Limited observation on several other species of plants indicates that some other herbaceous plants can be water soaked by spraying with a strong stream of water and that leaves in the sun water soak more rapidly than those in the shade.

### SUMMARY

Susceptibility of tobacco leaves to water soaking by a stream of water was determined largely by the degree of opening and condition of stomata. During the day stomata were open, and leaves could be water soaked easily and rapidly. At night, stomata usually were closed or nearly closed, and leaves water soaked only with difficulty. Wilting leaves and leaves shaded naturally or artificially water soaked slowly, and stomata were closed or nearly so.

Middle leaves of mature Burley plants water soaked more rapidly than tip leaves or basal leaves. Stomata were not fully developed on tip leaves. On basal leaves stomata were always closed or nearly so, some being deformed with degenerating guard cells.

The method described in this paper or some modification of it may be used as an indirect method for studying stomatal behavior.

# VENTRAL SURFACE SPECIALIZATIONS OF CONOCEPHALUM CONICUM 1

# Marjorie McConaha

THE THALLOID liverworts with limited tissue specialization are peculiarly dependent upon external conduction of water. A study has been made of Conocephalum conicum (L.) Dumort. with particular attention to its ventral differentiations in their relation to capillarity. This paper presents an analysis of these organs with respect to their number, position, and surface area, as well as consideration of their interrelations.

OBSERVATIONS.—The thallus of Conocephalum conicum is differentiated into a conspicuously thickened midrib and thin lateral wings. The midrib ranges from 1.0 to 1.4 mm. wide or one-eighth to one-tenth of the thallus width. It is about 0.35 mm. in vertical thickness in contrast to the thallus wings which taper from about 0.2 mm. near the midrib to a single row of cells at the margin of the thallus. Except for a few scattered rhizoids on the wings (more common in certain growth forms), the ventral appendages are localized on the under side of the midrib.

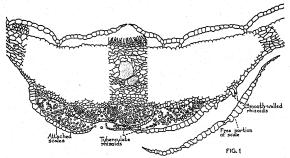

Fig. I. Transverse section of thallus of  ${\it Conocephalum conicum.}$ 

When the relative absorptive capacity of the ventral surfaces was tested by the application of basic dyes such as toluidin blue and neutral red, it was found that the dye was absorbed only by the scales and rhizoids. The dye did not penetrate into the superficial cells of the thallus and was not adsorbed by their walls. The absorptive areas of this plant are the surfaces exposed by the ventral organs which are localized on the midrib.

The under surface of the midrib bears two sets of scales. Each lateral series is formed by the oblique overlapping of individual scales in such a manner that the posterior portion of one is overlapped by the anterior portion of the next scale, two or three members of either series appearing in a given transverse section (fig. 1). Each scale consists of two

<sup>1</sup> Received for publication January 21, 1939.

The writer wishes to take this opportunity to express her sincere thanks to Professor R. B. Wylie for suggesting this problem and for his invaluable help and criticisms.

parts: (1) a free anterior portion with a circular appendage, and (2) the elongated portion which is attached by its outer edge to the midrib (fig. 2). The appendage soon withers, and 1-2 cm. back from the growing region only the wedge-shaped, attached portion remains.

The average length of a scale is about 5 mm., the attached portion tapering in width from about 0.5 mm. to a single cell at the posterior end. The surface area of an entire scale is approximately 1.8 sq. mm. The ratio of total scale surface to that of the ventral area of the midrib on which they are borne is 3.8:1. The area of the midrib region is thus increased approximately 380 per cent by means of

scales

A definite localization of the two types of rhizoids for Conocephalum was established by this study. The smooth-walled rhizoids arise from the midrib region covered by the free anterior portion of the scale, and not outside the scale as Cavers (1904) held (fig. 2, 3). They emerge laterally from behind the scales and extend downward to the substrate. The tuberculate rhizoids, on the other hand, arise from that part of the midrib covered by the attached portion of the scale and so are forced to lie nearly parallel to the midrib and within the channels formed between the overlapping scales. Since the rhizoid bases stain sharply with safranin, they may be easily distinguished from other cells of the midrib region, and, with the aid of a biobjective binocular, rhizoidal counts on measured areas of the midrib are readily made.

The total number of rhizoids per centimeter of midrib length ranged from 673 to 1102, with an average of 875, as determined by counts on ten samples from six different thalli. For the plant as a whole, smooth and tuberculate rhizoids are present on the midrib in about equal numbers. Although casual observation suggests that smooth rhizoids have a greater diameter, measurements show that the two types are equal in size, with an average diameter of 15.9 microns. However, they differ greatly in length; the average length of the smooth rhizoids is 6.9 mm., while that of the tuberculates is 16.48 mm. Since the two types occur in equal numbers, the mean rhizoidal length of 11.69 mm. was used in all calculations relating to these appendages. The superficial area of an average rhizoid is 583,915 sq. microns or 0.584 sq. mm. With an average of 87.5 rhizoids per square millimeter of ventral surface of the midrib, the ratio of rhizoidal area to the superficial midrib area on which they are borne is 51:1. The superficial area of the ventral midrib region, therefore, is increased 5100 per cent by rhizoids and 380 per cent by scales, or 5480 per cent by both sets of appendages.

[The Journal for May (26: 271-351) was issued June 7, 1939.] AMERICAN JOURNAL OF BOTANY, VOL. 26, No. 6, JUNE, 1939. While such absorptive areas are important, of perhaps greater significance is the relation of these appendages to the formation of a capillary system outside the plant. The external conduction of water along the ventral midrib may be demonstrated by applying a small amount of aqueous dye to the end of a thallus and watching its spread. Movement of the solution can easily be detected by coloration of absorptive surfaces of the scales and rhizoids as well as by the presence of dye in the interstices between these ventral organs. Conduction from base to apex of an average thallus requires only twenty to thirty seconds, due to rapid movement of liquid in the capillary spaces between the ventral surfaces.

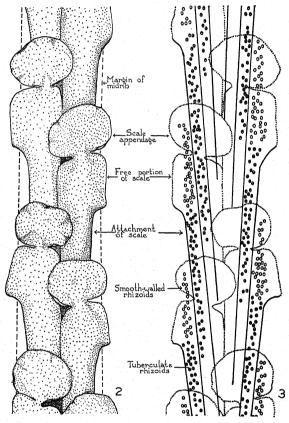

Fig. 2-3.—Fig. 2. External view of scales of Conocepha lum.—Fig. 3. Mirror image of fig. 2 showing insertion of scales and rhizoids.

Discussion.—The ventral specializations of the Marchantiaceae in relation to the distribution of external water, according to Kamerling (1897), were first emphasized by Kny (1890), who suggested the possibility of conduction within the wick-like rhizoidal fascicles. Cavers (1904) speaks of the retention of water within the narrow spaces between scales and rhizoids of Conocephalum conicum (Fegatella conica [L.] Corda). The added possibility of conduction was recognized by Bolleter (1905), who says of the rhizoids: "Indem sie stets dichte Bündel bilden, vermögen sie übrigens Wasser auch

kapillar zwischen sich festzuhalten und zu leiten, eine Wirkung, die durch die Schuppe, in deren Achsel sie entspringen, erhöht wird." A more detailed investigation of the external conduction of water was reported by Bowen (1935) for Fimbriaria blumeana Gottsche. She demonstrated the external conduction of dyes in the narrow interstices between scales and thallus but did not discuss the arrangement and surface relations of its ventral organs.

Concerning water absorption by the thalloid liverworts, there are the following references in Verdoorn's "Manual of Bryology" (1932). Garjeanne (p. 212) states that "in general, water is absorbed by thallus or leaves directly, this being one of the characteristics of the bryophytes." Buch (p. 67) says, "Die Wasseraufnahme durch die Rhizoiden ist eigentlich nur für die Marchantiaceae wichtig, deren Oberfläche ja meist nicht benetzbar ist." Czaja (1936), in testing the alkaline-membrane effect of absorptive tissues, found for Marchantia polymorpha L. that only the cell walls of rhizoids colored with toluidin blue; thallus cells remained unstained and therefore were regarded to be non-absorptive.

For Conocephalum conicum, my tests, using similar methods, show that absorption is limited to the ventral appendages and that the ventral cells of the thallus are non-absorptive. In contrast to Marchantia, absorptive organs of Conocephalum are localized on the ventral midrib rather than distributed over the entire surface of the thallus. For this reason, to the problem of absorption is added that of water distribution, in order that it may be made available to the absorptive surfaces of the whole plant.

Analysis of the midrib appendages of Conocephalum shows that the rapid movement of water along the thallus is greatly favored by the arrangement of the ventral organs. A complex capillary system is formed by the overarching and overlapping scales and the inclosed rhizoids. Since the tuberculate rhizoids arise under the scales, they are prevented from growing downward and are forced into a longitudinal position nearly parallel to each other beneath the several scales of each lateral series. These individual rhizoidal strands, with 40–100 rhizoids each, converge, forming a central capillary system which is continuous for the length of the thallus.

The smooth-walled rhizoids, which emerge laterally from beneath the free anterior portion of the scale, function in anchorage and for direct absorption. They may also serve as temporary lateral branches of the capillary system and supply water to the absorptive surfaces of the plant.

This external capillary retention and conduction of water in Conocephalum conicum may occur in the narrow interstices (1) between tuberculate rhizoids, (2) between rhizoids and their inclosing scales, (3) between rhizoids and the ventral surface of the midrib, (4) between smooth-walled rhizoids,

and (5) between all ventral surfaces and the substrate. The potency of this system for capillary conduction is suggested by the 5480 per cent increase in superficial area of the midrib region through its appendages. When the system is supplied with water, the loose arrangement of the ventral organs permits readjustments which make possible the maximum water retention; with diminishing water supply the surfaces may be brought closer together, thereby adjusting their spatial relations to capillary movement. By means of their ventral protected position, these ventral specializations make possible maximum water retention as well as increased absorptive surface without a concomitant water loss. External water conduction is of fundamental importance in the water maintenance of Conocephalum conicum.2

#### SUMMARY

In Conocephalum conicum (L.) Dumort. water absorption is limited to the ventral appendages.

<sup>2</sup> Since the submission of this paper for publication, Clee (1939) has reported investigations on water conduction in *Pellia epiphylla*. External conduction of water as a capillary film along the under surface of the thallus was found to be "exceedingly rapid," supplying water to the antheridia, archegonia, and developing sporophytes.

All ventral appendages are localized on the under side of the midrib. The area of this region is increased approximately 380 per cent by its scales and 5100 per cent by its rhizoids—together 5480 per cent.

Each scale consists of (1) a free anterior portion, with a circular appendage, and (2) a wedge-shaped portion which is attached by its outer margin to the

ventral surface of the midrib.

The smooth-walled rhizoids arise from the areas covered by the free anterior portions of the scales and readily achieve soil contact. The tuberculate rhizoids originate beneath the attached portions of the overarching and overlapping scales and are forced to assume a longitudinal position, forming strands beneath each scale and parallel to the midrib.

These rhizoidal strands and their overarching scales constitute a complex capillary system which extends the entire length of the thallus.

Rapid conduction of water along the ventral midrib region by external capillarity makes possible the distribution of water to the entire absorptive area of the plant.

# THE INFLUENCE OF SOIL NUTRIENTS ON DROUGHT RESISTANCE OF TWO-YEAR-OLD RED PINE <sup>1</sup>

Hardy L. Shirley and Lloyd J. Meuli

Observations during the last nine years indicate that droughts of sufficient intensity to cause losses to newly established forest plantations are the rule rather than the exception in the Lake States. In only one of these years did soils on the Chippewa National Forest, Minnesota, fail to dry

<sup>1</sup> Received for publication February 20, 1939.

Delivered before a joint meeting of the Society of American Foresters and the Ecological Society of America, at Richmond, Virginia, December 28, 1938.

Assistance in the performance of experiments, and in the analyses of results, was furnished by personnel of the Works Progress Administration. The statistical treatments used were suggested by R. H. Blythe, Jr., who also supervised the analyses. Help with Russian literature was furnished by S. R. Gevorkiantz.

to the wilting coefficient in the upper two or more inches. Depletion of moisture is particularly common in sandy soils covered with dense sod or low brush which, because they may readily be furrowed, are the areas most frequently chosen for forest planting. Successful planting of these sites is dependent upon using nursery stock with roots capable of penetrating to moist soil layers, and therefore able to evade drought, or upon using stock specially hardened to endure drought. The first requires stock capable of rapid root growth; the second, stock capable of resisting desiccation. Since the degree to which either quality can be induced is limited, best results are to be expected if

the stock possesses both of these characteristics.

Experiments performed during the past six years have shown that drought resistance can be induced in young conifers by exposing them during the growing season to periodic soil dryness and, furthermore, that resistance induced in this manner persists in part during the following season (Shirley and Meuli, 1939). These results were definite and convincing and in general agreement with similar tests on cereal plants reported by Russian workers.

The technique of testing drought resistance has not yet been standardized to the degree that technique for testing cold resistance has. It is not surprising, therefore, to find conflicting interpretations reported in the few papers which have appeared on the influence of mineral nutrients on drought resistance. For instance, using different species, different fertilizing techniques and different methods of estimating drought resistance, Dexter (1937) reports that fertilizers reduce drought resistance; Tumanow (1930), that fertilizers have no effect on drought resistance; and Semakin (1936, 1938), that fertilizers improve drought resistance. Auchter (1932) recommended application of fertilizers, particularly of nitrogenous fertilizers to

drought-injured orchard trees.

Specifically, Dexter (1937) found that rhizomes of quack grass dug from plots heavily fertilized with ammonium sulphate and sprouted in a germinator were more severely injured by exposure to drying for 8, 18, and 48 hours than rhizomes similarly treated but from unfertilized plots. Little difference in apparent drought resistance existed between fertilized and unfertilized rhizomes exposed to drying before being sprouted. Tumanow (1930) found that under conditions of moderate, pronounced, and maximum wilting, the water deficit in leaves and stems, the loss of leaf tissue on drying, and the yield in comparison with unwilted plants of oats and millet were unaffected by applying a fertilizer containing nitrogen, phosphorus, potassium, and sulphur to the light sandy soil in which the plants were grown. From this he concluded that drought resistance is little influenced by soil fertility. Semakin (1936) found that plants can be hardened against drought by exposing them to soil solutions of high concentration. In later experiments Semakin (1938) tested the effect of nitrogen, phosphorus, and potassium applied singly and the three together upon the behavior of barley and grape plants exposed for 6 to 10 days to soil dryness. Drought resistance, as determined by resistance to wilting, by ability to exhaust soil moisture, by osmotic concentration in leaves and stems, by resistance to loss in dry weight upon wilting, and by photosynthetic rate of plants in dry soil, was improved by applications of these mineral nutrients, particularly by applications of phosphorus and of phosphorus in combination with nitrogen and potassium. The nutrients were applied in relatively large amounts, 0.1 to 0.6 grams per liter of sand or soil. The concentrations resulting in maximum drought resistance caused a reduction in growth of barley, but not of grapes. Udolskaja (1934) found that nitrogenous fertilizers lowered the yield of wheat exposed to drought, whereas phosphate fertilizers increased the yield, increased the rate of photosynthesis, and increased the water-retaining capacity of the plant tissue above that of unfertilized plants.

Exploratory studies carried out by the writers in 1933 indicated that drought resistance of conifers was influenced by fertilizing practice. This lead was followed up in 1938 by two experiments designed to test the effects on drought resistance of different concentrations of nitrogen, and of phosphorus and potassium in the nutrient media. Red pine (Pinus resinosa) seedlings, grown for one year in the United States Forest Service nursery at Cass Lake, Minnesota, were used as experimental material.

Sand cultures.—In the first experiment, performed in a greenhouse at St. Paul, seedlings were potted in one-gallon, glazed jars filled with clean silica sand.<sup>2</sup> Analysis showed this sand to contain no available nitrogen and only a trace of available

phosphate.

The following basic nutrient solution was added to all cultures: MgSO<sub>4</sub> · 7H<sub>2</sub>O, 0.055 gram per liter; CaCl<sub>2</sub>, 0.107 gram per liter; H<sub>3</sub>BO<sub>3</sub>, MnSO<sub>4</sub> · 4H<sub>2</sub>O, and FeSO<sub>4</sub> · 7H<sub>2</sub>O, each 0.003 gram per liter. Nitrogen in the form of (NH<sub>4</sub>)<sub>2</sub>SO<sub>4</sub> was added at the rate of 0, 0.245, and 0.49 gram per liter; potassium and phosphorus as KH<sub>2</sub>PO<sub>4</sub> at 0, 0.29, and 0.58 gram per liter. The experiment was factorially designed having all possible combinations of the three levels of nitrogen with the three levels of phosphate (KH<sub>2</sub>PO<sub>4</sub>). To each of these, two watering régimes were added, making a total of 18 individual treatments. Four jars containing 7 seedlings each formed a unit for treatment. The total number of plants involved was 504.

The first nutrient treatment was applied on May 23, two days after potting was completed. Nutrients were applied once weekly, at one-half strength for the first month and at full strength thereafter. At each application sufficient solution was added to saturate the sand; the excess drained off through a hole at the bottom of the jar. Distilled water was added every second or third day until June 28. Thereafter, one group was watered to saturation daily or at two-day intervals, the second at threeor four-day intervals. The longer intervals were used in cloudy weather, the shorter ones in fair weather. The variations in moisture content of the sand were not followed. Aeration was ensured by alternate saturation and draining of the sand. In addition the cultures were aerated once with a tire pump. Treatments were continued until September 9 when the plants were lifted for drought tests. The two watering régimes caused no noticeable differences in appearance and no significant differences in survival, dry weight, or drought resistance;

therefore plants from corresponding nutrient treatments from the two watering régimes are hereafter considered to belong to the same treatment.

The total mortality during the 109-day period of nutrient treatment which preceded drought tests was 2 out of 168 plants in the 3 cultures without nitrogen, 6 out of 112 plants in the 2 cultures having nitrogen at single strength plus phosphate, and 106 out of 224 plants in the 4 cultures having nitrogen at double strength and nitrogen at single strength without phosphate. The color of plants receiving no nitrogen was yellow green, whereas that of those receiving nitrogen in single or double strength solutions was dark green. As to size, plants without nitrogen or without phosphorus and potassium were smaller, had shorter needles and more fibrous roots than those receiving all three nutrient elements. The average dry weights by nutrient levels, determined after the drought tests were completed, showed the plants in the N<sub>1</sub>P<sub>2</sub> group to be the largest (table 1).

The seedlings were repotted individually in cans containing sand at 5 per cent moisture content and exposed in the 1936 drought machine (Shirley and Meuli, 1939) at an air temperature of 37°C. and at a relative humidity of 25 to 30 per cent. After three days, the plants were removed, freed of soil,

the top and root of each weighed fresh, then dried for 48 hours at 105°C. and reweighed. The percentage moisture content after 3 days' exposure was used as an index of relative drought resistance. Experience has shown this to be closely correlated with the total length of time plants will survive in the machine. Moisture content varied from 29 to 130 per cent, depending on treatment. Plants having only 29 per cent moisture were obviously dead; those having 130 per cent were to all appearances in good condition. The moisture percentage, irrespective of treatment, was found to be inversely correlated with total dry weight, the regression coefficient being -20. To separate the size effect from the nutrient effect, the data were analyzed by the covariance method. This reduced the error and the differences between treatments but caused no significant change in their order. Differences due to nutrient levels were found to be significant beyond the .01 point. The average moisture contents by treatments, after adjusting for size, are shown in table 2.

Cultures without nitrogen or without potassium and phosphorus produced more drought-resistant plants than those in which all three of these elements were present. Additions of potassium and phosphorus improved resistance if no nitrogen was

<sup>&</sup>lt;sup>a</sup> Adjusted for plants equal in weight. <sup>b</sup> Means of 19 to 28 plants. Differences in moisture content of 21 per cent are significant at the 0.01 point.

present. With nitrogen supplied at single strength, double-strength phosphate solutions produced more resistant plants than single-strength phosphate. In fact, of the 4 cultures having both nitrogen and phosphate, the  $\rm N_1\,P_2$  treatment gave the highest survival during nutrient treatment, the largest plants and the highest moisture content at the end of the drought test. The  $\rm N_2\,P_0$  culture gave the lowest survival of all nutrient treatments and produced the smallest plants. These, however, were more drought resistant than the  $\rm N_1\,P_2$  group.

Top-root ratios were calculated but showed only a rough correlation with drought resistance. They were low in the  $N_0P_1$  and  $N_0P_2$  groups, intermediate in the  $N_0P_0$  and  $N_1P_0$  groups, and high in the

remaining groups.

NURSERY CULTURES.—The second experiment was carried out in the nursery at Cass Lake, Minnesota. The soil on an area approximately 15×45 feet was removed to a depth of 16 inches, thoroughly washed in a concrete mixer, and rinsed in a train of two sluice boxes. The coarse sedimented sand was returned to the nursery bed. This consisted of 4 per cent fine gravel, 17 per cent coarse sand, 33 per cent medium sand, 42 per cent fine sand, and 4 per cent very fine sand. Nitrate nitrogen was present at the rate of 2 pounds per acre, available phosphate at the rate of 50 pounds per acre. The area was divided into 18 beds 5×6 feet each, into which red pine seedlings were transplanted at a spacing of  $2\times 6$ inches. The experiment was arranged factorially having all possible combinations of ammonium sulphate at 0, 0.5, and 1.0 gram per square foot, with 20 per cent commercial superphosphate at 0, 1.67, and 3.33 grams per square foot, with frequent and infrequent watering, making a total of 18 individual treatments as in the greenhouse cultures. Ammonium sulphate was applied in solution; superphosphate was dusted on the surface and hoed into the soil. Both fertilizers were applied biweekly at one-half concentration from May 9 to June 18, and monthly at full concentration thereafter. The beds were thoroughly watered following each application. Differential watering was begun on June 18; thereafter one set of beds was watered daily, the other at intervals of 3 to 6 days depending on the weather. Soil moisture in daily-watered beds varied from 12 to 16 per cent; in infrequently-watered beds, from 5 to 16 per cent.

By the end of the summer, plants which had received no nitrogen were distinctly chlorotic; those receiving 0.5 gram per square foot had light green foliage; those receiving 1 gram per square foot had dark green foliage. Of the plants receiving nitrogen, those watered daily were lighter in color and smaller in size than corresponding plants watered infrequently. This indicates that daily watering must have caused leaching of the readily soluble ammonium sulphate from the sandy soil. No differences due to phosphate levels were discernible, an indication that the soil contained enough to support growth of red pine seedlings.

Five tests of drought resistance were made during the course of the summer in a new drought machine similar in construction to the 1936 model. Ten plants from each of the 18 treatments were used in each test. The seedlings were lifted, weighed fresh, potted in tin cans containing sand at 5 per cent moisture content, and placed in the machine where air temperature was held at 37°C, and relative humidity between 25 and 35 per cent. Each plant remained in the machine until dead, that is until its moisture content was reduced to approximately 50 per cent, as determined by shriveling of needles and increase in their rigidity. Plants so desiccated have invariably failed to recover when watered. The number of days survived is used as a criterion of drought resistance. Nonresistant plants have been found to die on the second or third day when available soil moisture approaches exhaustion; moderately resistant plants live 4 to 7 days, and highly resistant plants 8 days or longer.

The effect of fertilizers on drought resistance was clearly evident as early as July 11 when the first test was made. The magnitude of this effect became greater as the season progressed, and as the drought resistance of plants from all treatments improved. The fifth test, begun on September 12, gave the most striking results. In these tests also small plants appeared to be more drought resistant than large ones. The data were therefore analyzed by the covariance method to separate the size effect from the treatment effect. Again this analysis reduced the error and the differences between nutrient treatments but did not change their order. There was a tendency for drought resistance to decrease with increasing phosphate supply except in the minus nitrogen beds where additions of phosphate apparently improved drought resistance. Since these differences were not significant in either case, the three phosphate treatments are considered as though combined in the discussion which follows. Differences due to nitrogen supply and to the interaction of nitrogen supply and water supply were found to be significant at the .01 point (table 3). Ammonium sulphate reduced drought resistance in direct relation to the amount supplied. Infrequent watering definitely improved the resistance of plants deprived of nitrogen and probably of those supplied nitrogen at single strength; it had a tendency to decrease the resistance of plants supplied nitrogen at double strength. This is believed to be a reaction to higher nitrogen concentration in the infrequently watered, and therefore less leached, bed.

Discussion.—In both experiments drought resistance was found to be markedly reduced by applications of nitrogen. The effect proved to be the same irrespective of whether nitrogen was present only in sufficient concentration to result in optimum growth as in the nursery test or present in concentrations high enough to be somewhat toxic as in the greenhouse test. Only in the case of the  $N_2P_0$  treatment from the greenhouse, which was so toxic that only 23 out of 56 plants survived the period of nu-

trient treatment, did high concentration of nutrients increase drought resistance over that of corresponding plants from moderately fertilized cultures.

The fact that phosphate had a much more pronounced influence on drought resistance in the greenhouse cultures than in the nursery cultures is probably due to adequate phosphate being present in all nursery beds. Wilde (1938) reports that 50 pounds of available phosphate per acre, the amount found to be present in the washed nursery soil, is adequate for good growth of red pine in natural stands and by inference for red pine nursery stock also.

Until a more complete series of tests are available, in which internal nutrient concentrations are known as well as external supply, it seems presumptive to speculate on the mechanism involved. Emmert (1936) reports that soil dryness causes an accumulation of nitrates in tomato plants and a decrease in their phosphorus content. Possibly the lowered resistance of infrequently watered plants in the N<sub>1</sub> and N<sub>2</sub> nursery series may have been due in part to an increase in internal nitrogen concentration, though it seems more likely that it was due chiefly to the higher external concentration resulting from less leaching in the infrequently watered beds. It may also be pointed out that high nitrogen content has been found to reduce cold resistance (Dexter, 1935). No tests of cold resistance were made of the plant material used in these drought tests. It had been determined in preliminary experiments that exposing seedling conifers lifted in midsummer to low temperatures at night did not increase appreciably their resistance to drought. Semakin (1938) found that grape plants receiving extra potassium, though less drought resistant, were more cold resistant than those receiving extra phosphorus. The writers believe that it is not wise to press the analogy between drought resistance and cold resistance too closely, because as Maximow (1929) points out, there are plants cold resistant but not drought resistant, and others drought resistant but not cold resistant.

These experiments, and also those of Semakin (1938) indicate that drought resistance is influenced by the balance between nutrient elements as

well as by the concentration of nitrogen alone. The production of plants best able to survive natural droughts, such as occur in the field, is probably dependent upon maintaining an optimum combination of several nutrient elements.

Though nitrogen starvation increases the capacity to endure drought, it decreases growth. Large-sized plants with efficient leaf systems are necessary to supply food for rapid root penetration. This determines capacity to evade drought, which is often of greater importance than capacity to endure drought. Application of these findings to nursery practice should therefore be deferred until a schedule can be prescribed by which normal-sized and at the same time drought-resistant plants can be produced.

## SUMMARY

One-year-old red pine seedlings were cultured during the second growing season in pots and nursery beds supplied varying amounts of nitrogen, phosphate, and water. At the end of this period they were tested by exposure to controlled drought.

Increase in nitrogen content consistently resulted in a decrease in drought resistance.

Nursery-grown plants watered daily were less resistant than those watered at 3-day intervals if nitrogen was absent. With nitrogen present this effect was obscured because heavy watering resulted in leaching of nitrogen.

Phosphate supply also influenced drought resistance but its effect varied with nitrogen concentration. With no nitrogen present an increase in phosphate increased drought resistance. With nitrogen present this effect tended to persist, but the optimum combination of nitrogen and phosphate was not determined.

# A LOW COST CHAMBER FOR PHYTOHORMONE TESTS <sup>1</sup>

G. S. Avery, Jr., H. B. Creighton, and C. W. Hock

Because of the expense involved in providing the necessary constant-temperature constant-humidity rooms for carrying on quantitative research on plant growth hormones, studies in this field have been practicable in only a few institutions. Teachers of plant physiology desiring to offer quantitative phytohormone work to their students also have been handicapped by the lack of facilities. Even when properly controlled rooms are available, it is impossible to have many students working in the same room, because of the difficulty in controlling temperature, humidity, and carbon dioxide content of a room in which several persons are working.

The miniature control chamber described below, which may be constructed for fifty dollars or less, provides the necessary conditions as regards humidity and may be used in any darkroom with controlled temperature. If a constant-temperature room is not available, the chamber may be put in a temperature-regulated fiberboard case.

Description of chamber and inner rotating table.—The chamber consists of a circular sheet metal compartment 30 inches in diameter, tightly fitted with a removable cover (fig. 1, 2, 3). Attached to one side of the compartment is a small glass-covered vestibule which opens into the chamber by a removable door. The operator works on the test plants by putting his arms through holes in the front of the vestibule. The glass cover of the vestibule is set in a hinged frame, so that it may be opened as a door; this provides additional means of access to the chamber, via the vestibule, and may be used for larger objects whenever it is not desirable to remove the cover of the chamber.

The rotating table provides space for eight or nine dozen test plants (water culture), all of which may be reached readily through the small door be
1 Received for publication March 9, 1939.

tween the chamber and the operating vestibule. The rotating table with its supporting frame may be removed at will (fig. 1).

Specifications for construction.—The sheet metal outer chamber is of 24 gauge galvanized iron, the bottom double-seamed and soldered so as to be water tight. The vestibule is connected with the humid chamber by a soldered lap joint. The removable cover for the humid chamber is double-seamed and hemmed on the edge (snug fit). The door above the vestibule consists of a galvanized iron frame around double thick window glass (fig. 1, 2).

The supporting framework for the rotating table is made entirely of galvanized band iron  $1'' \times 1/8''$ . Top and bottom cross pieces are bent down at the ends and fastened to uprights with brass nuts and bolts. For support, bolts at the center bottom of the supporting framework extend to bottom of outer chamber (fig. 1, 3).

The rotating table has cross supports made of  $1'' \times \frac{1}{8}''$  galvanized angle iron cut back 1'' on the side and the overhanging 1'' top bent down. The outer hoop is of  $1'' \times \frac{1}{8}''$  galvanized band iron fastened to the bent-over ends of the angle iron by brass screws. The cross supports are covered with  $\frac{3}{8}''$  mesh hardware cloth soldered on same and extending to the hoop where it is also soldered (fig. 1, 3).

The axil on which the rotating table turns is made of  $\frac{3}{8}$ " brass rod, long enough to extend through top cover (for revolving from the outside, if necessary). The rod is turned down to  $\frac{3}{16}$ " for a distance of  $\frac{1}{2}$ " at the lower end, in order to form a bearing for the rotating table in the supporting framework (fig. 3).

The humid chamber, rotating table, etc., may be paraffined to prevent corrosion of the metal.

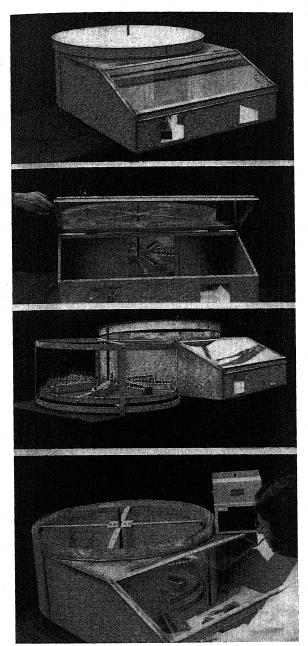

Fig. 1. Photographs of control chamber. Top: with lid on, showing operating vestibule and door leading from vestibule into humid chamber. Upper center: with lid off and hinged glass cover of operating vestibule raised. Lower center: rotating table with supporting framework, removed from control chamber; on rotating table note arrangement of zinc trays with water, and adjacent racks of Avena test plants. Bottom: showing position of operator when decapitating Avena test plants in vestibule. The door between vestibule and humid chamber is closed except when removing (or replacing) test plants from humid chamber.

TEMPERATURE CONTROL OF THE CHAMBER.—The chamber should be used preferably in a darkroom

in which the temperature is controlled at 78-79°F. Wherever a steady supply of steam is available, uniform heating of the darkroom can be accomplished with any existing radiator by installing thermostat-controlled electrically operated steam supply valves. The amount of radiation needed depends upon the heat loss from the room.

If electrical heating is needed or desired, the necessary number of electrical heating units can be readily installed to maintain the room at the desired temperature. These heating units, if controlled by a standard thermostat and relays, should regulate the temperature of the room to within + or - one degree F. No definite specifications for size of the electrical heating units can be given unless the size and construction of the room are known. To be heated economically by electricity, the room should be insulated.

If a fiberboard case (such as that illustrated in fig. 4) is constructed around the chamber, it may have the same electrical heating arrangement as described for a darkroom.

HUMIDITY CONTROL.—The volume of the chamber is such that eight or nine zinc trays  $1\frac{1}{4}"\times 1\frac{1}{4}"\times 8\frac{1}{2}"$ , approximately three-fourths full of water, will provide a relative humidity of 86–88 per cent at 78–79°F. This is the optimum humidity and temperature reported for "standard" Avena tests. When setting up the chamber in preparation for tests, the zinc trays (paraffin coated) should be filled with water already at a temperature of 78–79°. If this is done, the relative humidity in the chamber climbs to 88 per cent within 8 hours (fig. 5), whereas, if started with cold water, the humidity climbs slowly over a period of 15 hours. Figure 5 shows full thermohumidigraph records of conditions in the chamber during several tests.

In order to maintain a constant humidity in the operating vestibule while decapitating, applying blocks, and removing for photographing, paper towels thoroughly moistened are placed on the floor of the operating vestibule an hour or so before tests are started. If the towels show any sign of drying out during these operations, or later during photographing, they should be re-moistened.

As a precaution against any water being picked up by the racks of test plants during decapitation, etc., a dry block of wood large enough to act as a stand for a rack of test plants is placed in the vestibule during decapitation, etc. For the humidity to remain at known levels, as indicated in figure 5, the racks should be dry both when the experiment is set up and during subsequent operations. Any water clinging to the racks increases the evaporating surface, causing a rise in humidity within the chamber. Also, as a precaution against unduly increasing the humidity within the chamber, care must be exercised not to spill any water when the trays are placed on or removed from the rotating table. Such precautions are simple in practice.

ILLUMINATION.—Various types of illumination for the chamber may be used. The main points to

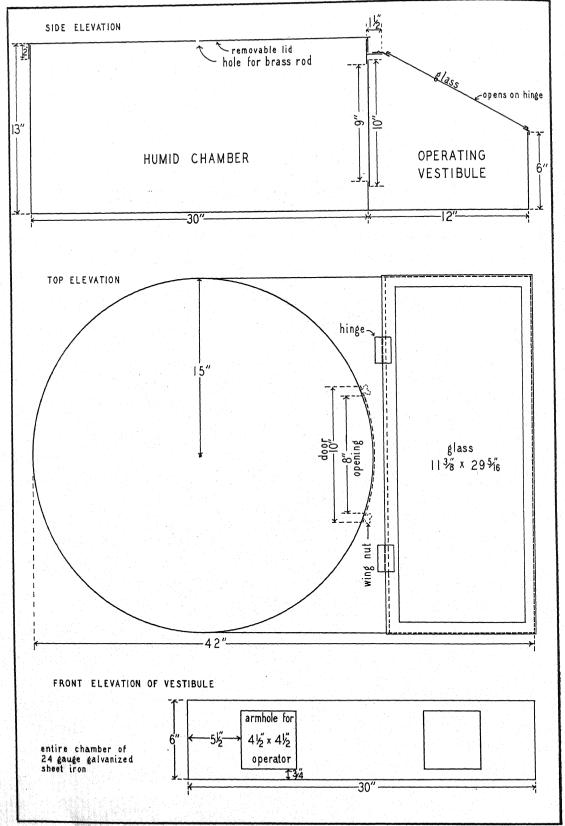

Fig. 2. Working drawings of top and side elevation of control chamber.

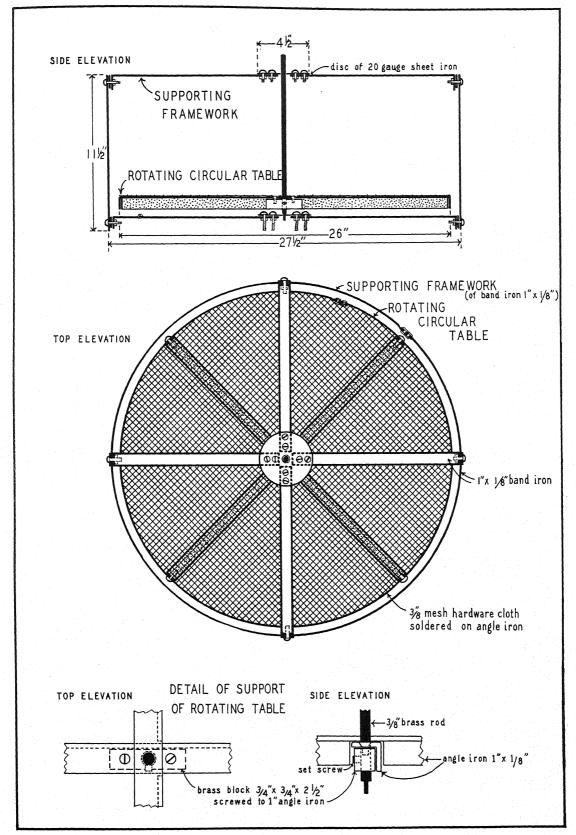

Fig. 3. Working drawings of top and side elevation of rotating table and its supporting framework.

be considered are, first, that the light be so placed that reflections from the vestibule window do not impair vision, and, secondly, that the temperature of the chamber is not raised. A simple source of light is an Eastman Safelight Lamp, size no. 2, in which has been placed a Corning Glass Co. red filter no. 246. Any other type of lamp providing phototropically inactive light is satisfactory, as long as the temperature in the chamber is not affected. For this latter reason and for best illumination, the lamp may be set directly upon the operating vestibule, rather than upon the chamber.

RESULTS OF TESTS WITH INDOLE ACETIC ACID.-The data given are the result of comparative tests in the control chamber and in the usual controlledtemperature controlled-humidity testing room. The accompanying table illustrates the results of tests on more than 100 doz. test plants, using both the "standard" method of Went (1928) and Skoog's "deseeded" method (1937).

The somewhat greater curvatures obtained in the regular test room may possibly be attributed to the

Table 1. Avena coleoptile tests in the control chamber and in the usual test room, using 3-indole acetic acid made up in 1.5 per cent agar, in the concentrations indicated. Results are given in "degrees curvature" of the test coleoptiles, each figure being the average of twenty-four coleoptiles.

higher humidity, the test room being, on the average, 5 to 10 per cent more humid than the control chamber. For the week of January 23, however, the relative humidity of the test room was about the same as for the control chamber; the Avena tests were also in close agreement. It is of interest to note that in these tests the curvatures obtained, per unit of indole acetic acid, are about four times greater with the "deseeded" test method than with the "standard" method.

SCHEDULE OF TEST METHODS .- "Deseeded" Avena method (with endosperm removed) (Skoog) .-The following time schedule was chosen as a convenient one:

First day, 9 a.m. Soak hulled oats 2-4 hours, then pour off water and set seeds, embryo side up, about  $\frac{1}{2}$  apart, in rows  $\frac{3}{4}$  apart, on moist filter paper in 150 mm. diameter Petri dishes. After a few hours exposure to light in the laboratory, place in 78-79°F. darkroom (5 or 6 p.m.), and allow to grow undisturbed until the third day.

Third day, 2 or 3 p.m. Set dishes of seedlings at approximately a  $60^{\circ}$  angle so coleoptiles will grow upward, and straight. 8 to 10 p.m. At approximately 60 hours of age, the coleoptiles should be 1.5 to 2 cm. in length. The endosperm is carefully broken off with the fingers. A small tuft of twisted cotton is wound around the region of the removed endosperm, and the seedling pulled carefully into the glass holder. At the time of pulling into the holders, the coleoptiles are so oriented that the broad side is parallel with the rack, hence the agar blocks are subsequently placed over a vascular bundle. After

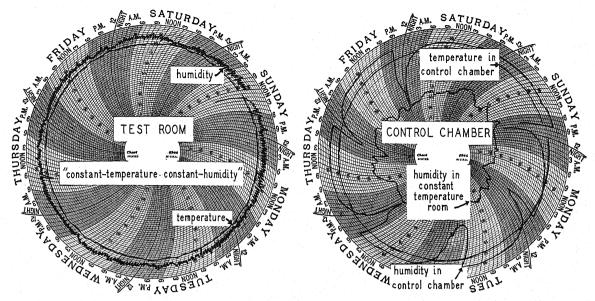

Fig. 5. Thermohumidigraph records of temperature and relative humidity in the control chamber and test room (week of Jan. 23). The humidity record of the room in which the control chamber was housed has been traced on the same recorder sheet with the data from the chamber. In the control chamber each sharp dip in the humidity curve indicates the time at which the lid was removed to set up a new experiment. The zinc trays for the "Monday" experiment were filled with cold tap water; note how slowly the humidity increases under such conditions. In all other experiments the trays were filled with water at a temperature of 78–79°F.

a little experience it is possible for the operator to merely feel the broad vs. the narrow side of the coleoptile and thus orient it quickly and properly. Upon completion of the "deseeding" operation, each rack of test plants is placed with the seedling roots immersed in a tray ¾ full of water (78-79°F.). The "deseeding" is done in the darkroom, outside the control chamber. When 8 or 9 racks of test plants have been "deseeded," they are carefully placed, together with the trays, on the rotating table in the humid chamber. The lid may be removed for this purpose, or they may be inserted through the door between the chamber and the operating vestibule.

Fourth day, 1 to 2 p.m. In the operating vestibule, 17-18 hours after "deseeding," decapitate as in the "standard" method and immediately apply agar blocks to be tested, then replace in humid chamber. Photograph 5 hours later.

"Standard" Avena method (Went).—This test is too well known to require mention of test schedule, but it may be pointed out that the test plants with endosperms still attached, are placed in the holders at the same time that the "deseeded" plants are placed in holders. After decapitation on the fourth day, forty minutes are allowed to elapse before application of agar blocks. Photographs are taken after 2 hours (Went originally stipulated 110 minutes). Schneider and Went (1938) have made available further information on this test.

## SUMMARY

A chamber is described for use in the Avena test for plant growth substances. It permits perfect humidity control if kept in a temperature controlled darkroom and thus obviates expensive humidity control equipment and maintenance expense. The chamber is large enough to care for 8 or 9 racks of Avena seedlings (each holding 12 plants) in water culture. Several control chambers may be housed in a single darkroom. Schedules are given for the "deseeded" and "standard" Avena methods (Skoog and Went) as used in comparative tests in the new control chamber and in the usual constant-temperature constant-humidity test room. The results of such tests on more than 100 dozen test plants are included.

# GRASS STUDIES. III. ADDITIONAL SOMATIC CHROMOSOME COMPLEMENTS 1

Etlar L. Nielsen

The work reported in this paper is a continuation of the investigations begun by Nielsen and Humphrey (1937). The material used in the study, taken from plants grown in the greenhouse, was fixed in chrom-acetic-formalin, the embedded material sectioned at  $12~\mu$  and stained with iodine-crystal-violet. The plants later were transplanted into the field where they were grown to maturity. The identifications were made with the aid of Hitchcock's (1935) "Manual of Grasses of the United States." The camera lucida drawings were made at a projected magnification of  $1500\times$ ,  $2100\times$ , or  $2600\times$ .

The micro-morphological measurements reported for the nuclear diameters were made upon nuclei in metabolic condition located in the meristematic region of the root tip. Fifty measurements were used to determine the average figure given for each case discussed. These and similar data for the chromosomes are summarized in table 1. Included in this table also are the Arkansas accession numbers, the seed or clonal source, and the original collector and year of collection if known.

FESTUCEAE.—Stahlin (1929) and Avdulov (1928) have reported complements of 42 and 56 chromosomes, respectively, for races of Bromus inermis Leyss. The writer has confirmed Avdulov's observations of 56 chromosomes in somatic tissue and examined material of an additional race of this series with complements of 70 chromosomes. The 56-chromosome race has thicker and shorter chromosomes and smaller nuclei than the 70-chromosome race (fig. 1, 2). Herbarium specimens prepared from the plants from which the cytological material was taken show little morphological difference other than a slight increase in size of the latter race. This is also true of other plants of these same selections now being grown in the grass nursery at this station.

Bromus marginatus Nees is composed of a series of races closely paralleling that of Bromus inermis. This species has previously been reported to have races with complements of 28 by Horton and Beck (1932), of 42 by Nielsen and Humphrey (1937), and of 56 chromosomes by Avdulov (1931). To this series of races has been added an additional one with a complement of 70 (fig. 3). A comparison of the members of the complements of the 42- and 70-chromosome races shows that the former race has thicker chromosomes and smaller nuclei. Unfortunately, no herbarium specimens were prepared of the 42-chromosome strain previously reported so that no gross morphological comparisons can be drawn.

Root tip cells of *Bromus commutatus* Shrad. and *B. secalinus L.* were characterized, respectively, by <sup>1</sup> Received for publication April 3, 1939.

Research Paper No. 646, Journal Series, University of Arkansas.

complements of 56 and 14 chromosomes (fig. 4, 5). Although the diameters of the chromosomes of both species were similar, the lengths of those of the former species varied from  $2.5~\mu$  to  $7.5~\mu$  as compared with  $3.5~\mu$  to  $6.0~\mu$  for the latter. No other significant morphological differences such as constrictions and satellites were detected. Avdulov (1928) had previously reported B. secalinus to have 28 chromosomes, a complement which was subsequently verified by Stahlin (1929) and Nakajima (1931). This new number for this species thus suggests another polyploid series in members of this genus.

Glyceria grandis S. Wats. was found to have 28 chromosomes (fig. 6), mostly about 0.5  $\mu$  in diameter and from 1.5  $\mu$  to 3.5  $\mu$  in length. The individual members of the complements are irregularly rod-like to U-shaped and show no distinguishing morphological characters. The nuclei averaged 8.1  $\mu$  in diameter

Chromosome complements of 40 were observed in Eragrostis curvula (Schrad.) Nees and E. sessilispica Buckl. (fig. 7, 8). Likewise, material from Eragrostis spectabilis (Pursh) Steud., which was previously reported by Humphrey (1937) and by Nielsen and Humphrey (1937) as having 42 chromosomes, has been reexamined by the writer and found to have a complement of 40 (fig. 9), which thus places the basic number of this species in accord with those of other species of Eragrostis herein reported and with those previously reported by Avdulov (1928, 1931) and Hagerup (1932). The complements studied were made up of members characteristically about  $0.3 \mu$  in diameter which ranged from 1.0  $\mu$  to 2.2  $\mu$  in length. Their shape is generally rod-like, and they show no signs of such morphological features as constrictions. The average nuclear diameters were 7.9  $\mu$  for E. curvula, 8.0 μ for E. sessilispica, and 12.0 μ for E. spectabilis.

The Festuceae just reported fall into two groups as shown by these species of Bromus, Glyceria, and Eragrostis. Bromus and Glyceria have rather long, sometimes rod-like, but more often vermiform to U-shaped chromosomes characteristically in multiples of 7; Eragrostis has short, more regularly rod-shaped or slightly curved chromosomes occurring in multiples of 10. Although these observations, and a majority of those recorded for other species of this tribe, indicate these distinct groups, there are some records that multiples of other numbers also occur in the tribe. Avdulov (1928, 1931) reported diploid numbers of 18 in Melica altissima L., M. ciliata L., M. micrantha Boiss. and Hohen., and M. nutans L. Kattermann (1930) found these numbers correct for M. altissima and M. nutans, and Hunter (1934) verified the report of 18 chromosomes in M. altissima.

Hordeae.—The complements of Elymus canadensis var. robustus (Scribn. and Smith) Mackenz. and Bush, E. Macounii Vasey, and E. sibiricus L. each have 28 members (fig. 10, 11, 12). All appear alike, being long and often vermiform to U-shaped in outline. Those of E. Macounii are mostly about 0.5  $\mu$  in diameter as compared with 0.8  $\mu$  in the other species here considered. They range from 2.0  $\mu$  to 7.0  $\mu$  in length. Average nuclear diameters for the species studied varied from 7.8  $\mu$  to 11.5  $\mu$ .

These observations and many of those recorded in literature for other species of this tribe indicate that 7 is the prevalent basic number of the group. Deviations from this number have been found by Avdulov (1931), who reported a complement of about 36 chromosomes in Lepturus incurvatus Trin. (Pholiurus incurvatus (L.) Schinz. and Thell.) and one of 26 in Nardus stricta L.

AGROSTIDEAE.—Avdulov (1931) estimated the chromosome number in *Calamagrostis epigeios* (L.) Roth to be 70. The present writer found this species also may have the tetraploid number of 28 (fig. 13). One pair of chromosomes has well-defined submedial constrictions. The members of the com-

plement average slightly less than 0.5  $\mu$  in diameter and vary in length from 2.0  $\mu$  to 4.0  $\mu$ . The average nuclear diameter is 9.7  $\mu$ .

Agrostis exarata Trin. has 28 chromosomes (fig. 14)  $0.5~\mu$  in diameter varying from  $1.5~\mu$  to  $3.5~\mu$  in length. They are either rod-like to U-shaped in form, with none of the members showing distinguishing structural characters. The nuclear diameters

average 8.0 μ.

Sporobolus cryptandrus (Torr.) A. Gray was found to be a diploid species with 18 chromosomes, and S. heterolepis A. Gray an octoploid with 72 members in its complement (fig. 15, 16). The chromosomes of S. cryptandrus are rod-like to U-shaped in form, usually about  $0.7~\mu$  in diameter and  $2.5~\mu$  to  $6.0~\mu$  in length. Well-defined subterminal and submedial constrictions and a pair of satellites were observed. The nuclear diameters averaged  $7.8~\mu$ . The chromosomes of the S. heterolepis material studied were similar in form to those of S. cryptandrus but showed no morphological peculiarities. Their average diameter was  $0.5~\mu$ , and the lengths varied from  $1.0~\mu$  to  $3.9~\mu$ . The nuclear diameters averaged  $10.5~\mu$ .

Stipa pulchra Hitch. and S. columbiana Macoun, respectively, are hexaploid with 66 chromosomes and tetraploid with 44 chromosomes (fig. 17, 18). In S. pulchra the chromosomes are slightly less than 0.5  $\mu$  in diameter and from 1.0  $\mu$  to 3.0  $\mu$  in length. Two pairs of the usually rod-like to U-shaped chromosomes have deep subterminal constrictions. The average nuclear diameter was calculated as 10.0  $\mu$ . The chromosomes of S. columbiana are very similar to those of S. pulchra but average slightly over 0.5  $\mu$  by 1.5  $\mu$ . No significant variations in their morphology were observed. The diameter of the nuclei of

S. columbiana averaged 7.6 μ.

That there are exceptions to these basic numbers of 7, 9, and 11 found in the species of the tribe Agrostideae has been indicated by other workers. Thus Avdulov (1928, 1931) reported diploid numbers of "about" 40 chromosomes in Muhlenbergia glomerata (Willd.) Trin. (M. racemosa (Michx.) B. S. P.), of 40 in M. mexicana (L.) Trin. and in M. umbrosa Scribn. (M. sylvatica Torn.). Humphrey (1937) and Nielsen and Humphrey (1937) reported finding 42 chromosomes in somatic tissue of Muhlenbergia pungens Thurb. However, the present writer has rechecked material of this spe-

cies and found it to have 60 chromosomes (fig. 19). The members of the complement are irregular in form, varying from 1.0  $\mu$  to 3.5  $\mu$  in length, and are approximately 0.3  $\mu$  in diameter. Several pairs have medial or subterminal constrictions, and one pair of satellites was observed. Further, Avdulov (1928) reported complements of 24 in Oryzopsis miliacea (L.) Benth. and Hook., 24 in O. virescens (Trin.) Beck, and 38 in Urachne trichotoma (Nees) Trin.

Chlorideae.—Avdulov (1931) reported the somatic chromosome number of Buchloë dactyloides (Nutt.) Englem. to be 60. All the figures studied by this writer have 56 short and predominantly straight chromosomes mostly less than  $0.5 \mu$  in diameter and  $0.7 \mu$  to  $2.0 \mu$  in length (fig. 20). The

nuclear diameters average 10.1 μ.

Other instances somewhat comparable to that indicated in Buchloë occur in other genera and species of this tribe. Complements of 56 and 60 have been independently observed and reported to occur within species of Bouteloua and Spartina. Avdulov (1931) observed 40 chromosomes in Bouteloua gracilis (H. B. K.) Lag. Humphrey (1937) and Nielsen and Humphrey (1937) reported that Americangrown material of the same species had 42 chromosomes. Fults (1938), in personal correspondence to the writer, stated, "First, in regard to blue grama-I have found complements ranging all the way from 14 to apparently about 77, some of them being aneuploids and some of them being euploids. I have some meiotic figures showing the association and distribution of chromosomes in the first meiotic divisions and have found spindles with apparently all manner of types of association and distribution." In the genus Spartina, Avdulov (1928) observed complements of 40 in S. Schreberi F. Gmel., and of 80 to 90 in S. cynosuroides (L.) Roth. Huskins (1930) observed 70 chromosomes in S. alternifolia Lois, 56 in S. stricta (Ait.) Roth, and 126 in S. Townsendii H. and J. Groves. In 1929 Church reported finding 14 bivalents in S. pectinata Link (S. Michauxiana Hitch.) and 14 bivalents and 14 univalents in S. alternifolia var. glabra (Muhl.) Trin. Some species of the genus Chloris also have complements occurring in multiples of 7 and 10. Avdulov (1928) reported finding 20 chromosomes in C. barbata (L.) Swartz (C. inflata Link) and C. Gayana Kunth and 40 in C. acuminata Trin. (C. distichophylla Lag.), C. cucullata Lag., and C. truncata R. Br. In 1931

<sup>\*</sup> In reproducing this plate the lineal dimensions have been reduced approximately one-half.

he reported observing 80 chromosomes in C. submutica H. B. K., 40 in Trichloris mendocina (Phil.) Kurtz. The same year he also reported 18 chromosomes in Eleusine indica (L.) Gaertn., 36 in E. corocana (L.) Gaertn., and 14 in Beckmannia eruciformis Hook. Rau (1929) had previously reported the "probable" diploid number in the root tips of E. corocana to be 36. Krishnaswami and Ayyangar (1935) confirmed these reports for E. indica and E. corocana and reported haploid numbers of 18 in E. brevifolia R. Br. and 17 in E. aegyptica Desf. Nielsen and Humphrey (1937) observed 14 chromosomes in Chloris virgata Swartz and in Beckmannia syzigachne (Steud.) Fern.

Paniceae.—Two cytogenetic races of Paspalum Urvillei Steud., possessing complements of 40 and 60 chromosomes, respectively, were investigated (fig. 21, 22). The chromosomes of the former race were slightly larger than those of the latter, otherwise no visible difference between the members of the complements was observed. The nuclei of the latter race were found to be the larger. A comparison of the plants growing under field conditions shows that the race with the larger chromosome number is characterized also by more robust plants. In addition to the coarser culms and slightly longer racemes, the plants of the 60-chromosome race were pubescent on the sheaths, particularly along their margins, whereas those of the 40-chromosome race were glabrous excepting for a slight trace of pubescence upon the very lowermost sheaths.

Three species of Panicum were investigated. Of these P. anceps Michx. and P. Lindheimeri Scribn. are diploid species each having 18 somatic chromosomes, while P. texanum Buckl. is tetraploid (fig. 23, 24, 25). The individual chromosomes are morphologically similar, being for the most part either rod-shaped or somewhat crescent-shaped in form. Those of P. anceps were slightly less than  $0.5 \mu$  in diameter and  $1.5 \mu$  to  $3.5 \mu$  in length. The nuclei average  $5.0 \mu$ . P. Lindheimeri is intermediate, with chromosomes  $0.5 \mu$  in diameter,  $1.5 \mu$  to  $2.5 \mu$  long, and nuclei  $7.2 \mu$  in diameter. P. texanum has the largest chromosomes of the three species. They average  $0.7 \mu$  by  $1.5 \mu$  to  $5.0 \mu$ , and its nuclei are  $9.5 \mu$  in diameter.

These species of Panicum and Paspalum fall into two series with basic numbers of 9 and 10, respectively. In regard to other members of this tribe Karper and Chisholm (1936) reported observing 14 chromosomes in Pennisetum glaucum (L.) R. Br. Likewise, Church (1929) reported 42 chromosomes in Echinochloa crusgalli (L.) Beauv. and 56 in its variety frumentacea W. F. Wright. However, Avdulov (1931) reported observing 54, and Hunter (1934) found 36 chromosomes in what is presumably this same variety of Echinochloa.

Andropogoneae.—In 1929 Church reported finding 60 chromosomes in Andropogon furcatus Muhl. (A. provincialis Lam.). The writer has confirmed this observation (fig. 26). The figures examined showed very little difference among the in-

dividual members of the complement other than variations from short rod-like to strongly U-shaped bodies. They are prevailingly about 0.7  $\mu$  in diameter and vary from 2.0  $\mu$  to 4.0  $\mu$  in length. The nuclei average 9.0  $\mu$  in diameter.

Andropogon Hallii Hack., as it appears in the field, is exceedingly polymorphic, some races appearing to blend gradually with certain races of A. furcatus. Two of the six distinctly different morphological types selected from a single blowout in the sandhills near Inez, Nebraska, yielded material suitable for cytological study. Complements of 60 and 70 chromosomes were observed (fig. 27, 28) in selections No. 35 and No. 33, respectively. As is indicated in table 1, the individual chromosomes are nearly alike both in diameter and length. The nuclear diameters in the 70-chromosome race are slightly larger than in the 60-chromosome race. A comparison of fruiting plants of these selections indicates the following morphological differences distinguish the two races:

## No. 33

Lowermost leaf of fruiting culm 0.7 to 0.8 cm. wide, glabrous.

Pedicels of sterile spikelets usually less than 5 mm. long, pubescence sparse, white on growing plants.

Caryopsis mostly over 5.5 mm. long, slender.

Sterile spikelet awns 5 to 7 mm. long.

# No. 35

Lowermost leaf of fruiting culm 1.0 to 1.1 cm. wide, densely pilose.

Pedicels of sterile spikelets mostly more than 5 mm. long, pubescence dense, dark yellow on growing plants.

Caryopsis mostly less than 5 mm. long, plump.

Sterile spikelet awnless.

Two races of Andropogon scoparius Michx. were found to be characterized by complements of 40 chromosomes, which differ somewhat in structure. In one race, No. 856, no striking morphologic irregularities in chromosome structure were found, while the second race, No. 848, had one pair of deep subterminally to submedially constricted chromosomes. An examination of the other data given in table 1 and figures 29 and 30 indicates a well-defined difference in chromosome size and a small difference in the nuclear diameters. Growing plants and herbarium material taken from these selections show the following morphological differences characterize the two races:

## No. 848

Pilose lower sheaths.

Foliage dense and leafy.

Inflorescence loose and more erect.

Plant somewhat glaucous. Spikelet pubescence about 3 mm. long.

No. 856

Glabrous lower sheaths. Plant with sparse foliage. Inflorescence dense and spreading.

Plant not glaucous.

Spikelet pubescence about 2.7 mm. long.

A situation closely paralleling the case just reported was found to exist in *Andropogon saccharoides* Swartz, of which two cytogenetic races, characterized by 60 and 70 chromosomes, respectively,

were studied (fig. 31, 32). The data given in table 1 show that the 60-chromosome race, No. 860, has slightly thicker chromosomes, which vary from 1.0  $\mu$ to 4.0 \(\mu\) in length, as compared with the slightly thinner members of the 70-chromosome race, No. 859, which range from 1.5  $\mu$  to 3.5  $\mu$  in length. In 1931 Avdulov reported the diploid chromosome number of this species as 60. An examination of herbarium material taken from these plants showed the following differences:

#### No. 859

Plant with coarse culms, abundant foliage.

Lower sheaths pilose.

Awns mostly about 2 cm.

Terminal racemes about 4 cm. long.

# No. 860

Plant with fine culms, sparse foliage.

Lower sheaths glabrous.

Awns mostly about 1.4 cm. long.

Terminal racemes about 3.5 cm. long.

It may also be significant that No. 860 was heavily infected with Tolyposporium bullatum Schr., whereas No. 859, which was grown on the adjoining plot in the nursery, was free from the fungus.

Root-tip material of Andropogon perforatus Trin. showed complements of 80 chromosomes (fig. 33). Their form varies from rod-like to U-shaped in outline. They average  $0.5 \mu$  in diameter and range from 1.5  $\mu$  to 5.0  $\mu$  in length. The average diameter of the nuclei is 9.7  $\mu$ .

In this tribe all the observed chromosome complements were in multiples of 10. That species with complements not in multiples of 10 occur in the Andropogoneae is indicated by Bremer's (1934) report of finding 38 chromosomes in Miscanthus japonicus (Thumb.) Anderss., by Church's (1929)

report of 42 chromosomes in M. sinensis Anderss. and by Hunter's (1934) observation of 64 chromosomes in M. saccharifer (Anderss.) Benth. Other deviations from the basic number 10 have been reported by Avdulov (1931), who found 54 chromosomes in Rottboellia glandulosa Trin. (Manisuris glandulosa Trin.), and by Kuwada (1919) who reported observing 68 chromosomes in Ischaemum anthephoroides Miq.

#### SUMMARY

The diploid chromosome numbers in 34 races belonging to 28 species of the Gramineae are reported. The basic numbers occurring in the species studied are indicated, and attention is called to a few species with complements in multiples of numbers other than those common in the particular tribe concerned. In the study of species of the Chlorideae, several species are indicated wherein chromosome complements in multiples of both 7 and 10 have been reported.

Two new races, both characterized by 70 chromosomes, were observed in Bromus marginatus and in B. inermis, and one race with a diploid complement of 14 was found in B. secalinus. These complements appear to be new for the polyploid series occurring

in those species.

Complements of 40 and 60 somatic chromosomes were observed in races of Paspalum Urvillei, and others of 60 and 70 chromosomes were observed in both Andropogon Hallii and A. saccharoides. The vegetative features of these races are compared.

The findings are presented in table 1.

# STRUCTURE AND GROWTH OF THE SHOOT APEX OF CYCAS REVOLUTA $^{1}$

Adriance S. Foster

RECENT STUDIES on the shoot apex of vascular plants emphasize our inadequate knowledge of the fundamental nature of growth in terminal meristems. In particular, the investigations of Korody (1937), Härtl (1938), and Foster (1938) have clearly shown the complex interrelationship between the structural pattern and the distribution of growth in the meristem as a whole and its bearing on organ and tissue differentiation in the shoot. It is all too evident, however, that the classical concept of "primordial meristem" needs serious re-examination along broad comparative lines. For example, such phenomena as mitosis, cytokinesis, vacuolation, and cell enlargement are obviously concomitant with growth and differentiation, but their interrelationships in apical meristems at present are obscure and extremely complex.

The shoot apex of gymnosperms affords unusually favorable material for studies in this field because of the marked segregation in many genera of cell zones distinguished by such features as reaction to stains, frequency of mitosis, planes of division, and relative thickness of walls. In the present article, the results of a study on the shoot apex of several cycads are described. Since cycads possess a number of unique and primitive morphological characters, a preliminary exploration of their apical meristems should produce data of considerable interest when viewed comparatively with the situation in conifers (Korody, 1937), Ginkgo (Foster, 1938), and the angiosperms (cf. references in Foster 1936, 1938). The major emphasis in this study has been given to the shoot apex of seedlings and adventitious buds of Cycas revoluta Thunb. A less intensive examination has been made of the shoot tips of embryos, seedlings, and adult plants of Zamia floridana A.DC.

Doubtless the great difficulty of securing an abundance of critical material is responsible for the meagre literature on the structure of the shoot apex in cycads. The earliest account was given by Hofmeister (1857, taf. VII, fig. 12), who depicted a surface view of the shoot tip of Zamia longifolia to illustrate his belief in the existence of a triangular apical cell. No description is furnished, however, and his figure does not support his own interpretative received for publication April 4, 1939.

tion. A more detailed account of the presumptive apical cell in the seedling apex of Ceratozamia sp. was given by Dingler (1882, p. 30-33; taf. I, fig. 1-4), but the entire structure of the meristem is not described or figured. In contrast to Hofmeister and Dingler, Strasburger (1872, p. 335-336; taf. XXV, fig. 35-36) found no evidence of a single apical cell in the apex of adventitious buds of Cycas revoluta. He concluded that new cells originate from two superposed tiers of initials, the upper producing the dermatogen-periblem region, the lower the "massive plerome." Strasburger's general viewpoint was supported by Warming (1877, p. 119) for Ceratozamia longifolia and Cycas circinalis, by Bower (1884, p. 584) for Cycas Seemanni, and was adopted by DeBary (1884, p. 14) in his compendium on anat-

Within recent years, many studies have been made on the embryo, seedling, and adult shoot of various cycads without, however, appreciably advancing our knowledge of the growth and structure of the shoot apex (cf. bibliographies in Schuster [1932] and Chamberlain [1935]). Indeed, as far as the writer is aware, Thiessen (1908, p. 363; pl. XXV, fig. 8) is the only investigator who has attempted a description of the entire cellular structure of the apex. Working on the embryo of Dioon edule he concluded that the procambium, which is "the most active meristematic region of the stem," arises very near the growing point and that the pith "terminates in a tier of cells against the epidermis." Chamberlain (1910) emphasizes the "late differentiation" of dermatogen, periblem, and plerome regions in the shoot tip of the embryo of Dioon edule but gives no information on the structure of the terminal meristem of the seedling or adult plant of this species. Other workers (Dorety, 1908, 1909, 1919; Matte, 1909) entirely neglect the organization of the apical meristem.

MATERIALS AND METHODS.—The materials used in this investigation were furnished by the following individuals to whom grateful acknowledgment is made: Mr. Robert MacMillan of the City Nursery of Pasadena, California, for about five dozen two-year old seedlings of Cycas revoluta; Mr. Louis B. Downs, head gardener at Central Park, Pasadena, for his assistance in obtaining numerous adventi-

tious buds of *Cycas revoluta*; Dr. W. S. Phillips of Miami University, Coral Gables, Florida, for seeds and many fine adult plants of *Zamia floridana*; and Professor C. J. Chamberlain, University of Chicago, for several seedlings of *Zamia floridana*.

The same methods of fixation, staining, and illustration employed in my study of Ginkgo (Foster, 1938) were adopted. Serial transverse and longitudinal series were cut at 6 and 8 microns, the former thickness proving more satisfactory. Great difficulty was experienced in securing perfect series through the apex of adventitious buds of Cycas revoluta, even after removing the majority of the cataphylls. The use of a water-cooling device for knife- and block-carrier (cf. Chamberlain, 1932, p. 113) was found to be essential. I am indebted to one of my students, Mr. Ernest Ball, for planning the construction of this attachment.

Thanks are due my wife for her usual invaluable assistance with the illustrations. I am further indebted to the Board of Research of the University of California for a grant during the investigation.

GENERAL MORPHOLOGY OF THE BUDS OF CYCAS REVOLUTA.—In the two-year-old seedlings used for this study, the two cotyledons were still attached to the gametophyte of the seed, and the prominent conical terminal bud consisted of an outer series of tough cataphylls, one or two expanding or mature pinnate foliage leaves, and a highly variable number of developing foliar primordia. The adult cataphyll in C. revoluta consists of a massive sheath bearing a conspicuous median pointlet which morphologically represents an undeveloped lamina. In the dissection of about 40 buds for histological study it was observed that the early stages in ontogeny of cataphyll and foliage leaf appeared remarkably similar, at least externally, the principal distinction being the early appearance in the foliage leaf of the initials of the lateral pinnae. Utilizing this criterion, the foliar structures surrounding the shoot apex in the illustrations in this paper are regarded as cataphyll primordia. The general structure of the adventitious buds developing on the trunks of C. revoluta is similar except that the cataphylls are larger and more numerous and the foliage leaves tend to be arranged in definite "crowns." According to Stopes' (1910) observations on cultivated specimens of C. revoluta growing in Japan, the adventitious buds arise from the inner living tissue of the persistent leaf-bases of the trunk and are not connected in any way with the axis at first. A histogenetic study of the origin and early development of such buds would be of considerable interest. Stopes concludes that "the behavior of the buds makes it clear that probably the great majority of 'branched' plants are simply those in which one or more of these adventitious 'buds,' developed from the leaf-bases, had grown till it rivalled the main axis."

When viewed in median longisection, the shoot apex of seedlings typically has the form of a promi-

nent asymmetrical cone which is almost completely overarched by the adjacent cataphyll primordia (pl. I, fig. 1). In these respects, it contrasts markedly with the slightly convex and less extended shoot apex of Ginkgo (Foster, 1938, p. 533, fig. 1-2). The apex of adventitious buds of C. revoluta is much larger than that of the seedling and appears as a rather symmetrical blunt cone which, as was emphasized by Strasburger (1872), is depressed between and overarched by the adjacent leaf primordia (pl. I, fig. 6).

ZONAL STRUCTURE OF THE SHOOT APEX - The embryonic tissue of the shoot apex of seedlings of C. revoluta is not uniform in its structure or reaction to stains but on the contrary exhibits a characteristic zonation. In median longisection it is evident that a prominent core of relatively large, irregularly-arranged lightly-stained cells extends through the center of the apex, terminating as a distinct zone near or at the surface of the latter (pl. I, fig. 1, 2, 5). This internal core, which will be designated as the central tissue, is completely surrounded by a zone of peripheral tissue, composed of somewhat smaller cells with deeply-stained protoplasts (pl. I, fig. 1-5). An examination of numerous longisections demonstrates that these two well-defined tissuezones do not arise from separate tiers of initials. On the contrary, they originate from a single terminal group of initial cells which divide, apparently in no fixed sequence, both anticlinally and periclinally.

Figure 1 represents schematically the writer's interpretation of the distribution of growth in the peripheral and central tissue-zones of the apex. This diagram is based upon a detailed study of the orientation of mitotic figures, the relative frequency of new periclinal and anticlinal walls, and the degree of cell enlargement, in both longitudinal and transverse sections of many apices. Growth in the core of central tissue (zone II) is predominantly anticlinal with respect to the surface of the apex and is associated both with the division and highly irregular enlargement of the cells (pl. I, fig. 2-5). In contrast, the peripheral tissue (zone III) constitutes a zone typified by marked centrifugal growth in thickness chiefly resulting from repeated periclinal and anticlinal divisions in the surface cells and their derivatives on the flanks of the apex. In figure 1, the demarcation between these two zones is shown by the broken lines. It must be emphasized at this point, however, that such a demarcation is to some extent arbitrary, since many preparations conclusively show how irregular groups of cells, at the inner boundary of the peripheral tissue, may originate from the central tissue (fig. 4d-f, 6d, 7e). Under such circumstances, the relative depth of the peripheral tissue may be expected to vary somewhat in various apices, apparently in relation to fluctuations in the degree of radial expansion of the central tissue at a given level.

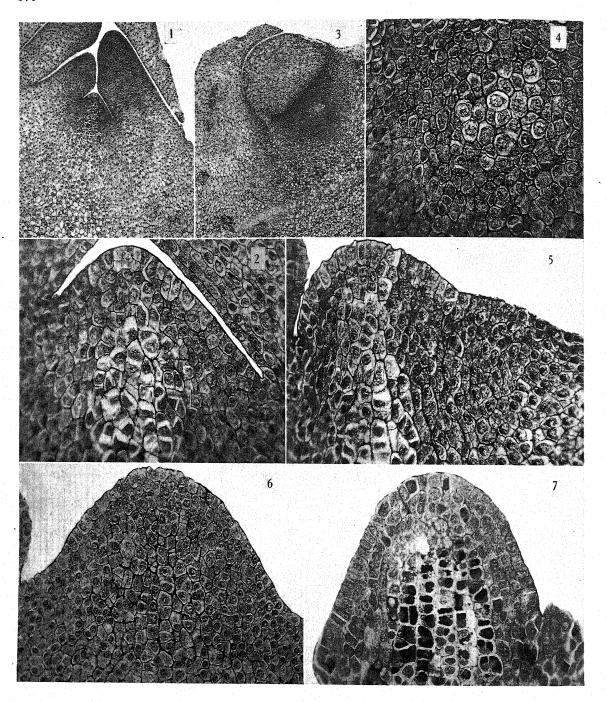

Plate I, fig. 1-7.—Fig. 1. Approximately median longisection of a seedling bud of Cycas revoluta showing the asymmetrical shoot apex overarched by the two youngest cataphyll primordia. The deeply-stained peripheral tissue of the shoot apex contrasts markedly with the prominent core of central tissue from the base of which the broad pith originates. Small granular bodies in the pith cells are starch grains. The procambial tissue, at each side of the pith, differentiates from the inner and lower portion of the peripheral tissue. Note the procambial tissue in the lower portion of the cataphyll primordium at the right and the two leaf-trace "girdles" in the cortex at the lower right of the figure.  $\times 36.5$ .—Fig. 2. The shoot apex of fig. 1 at higher magnification ( $\times 217.5$ ), illustrating the differences in size, arrangement, and staining reactions of the cells of central and peripheral tissue. Note the thickened areas of walls particularly in the central tissue and the active centrifugal growth in thickness of the peripheral tissue. This section is adjacent to the one shown in text fig. 6d.—Fig. 3. Transection of seedling bud of Cycas revoluta, 176 microns from surface of shoot apex, illustrating the clearly defined central tissue (small central group of lightly-stained cells) completely surrounded by the deeply-stained peripheral tissue. Note the leaf-trace "girdles" in the cortex at

With this general description of the distribution of growth in the shoot apex as a basis, a detailed account of the cellular structure of the meristem can now be given.

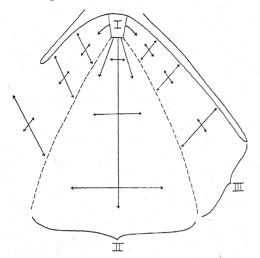

Fig. 1. Diagram illustrating the zonal structure and the distribution of growth in the shoot apex of seedlings of Cycas revoluta. Zone I is the apical initial group from the cells of which by anticlinal and periclinal divisions the peripheral tissue (zone III) and the core of central tissue (zone II) originate. The approximate cytological demarcation between zones II and III is represented by the broken outlines. In zone III, active centrifugal growth in thickness (long double arrows perpendicular to the surface) dominates over the less conspicuous growth in surface (smaller double arrows). The growth in zone II is predominantly anticlinal with respect to the surface of the shoot apex (long single arrow) but is obscured by progressive centrifugal expansion, as illustrated by the increasing length of the three double arrows.

APICAL INITIAL GROUP (zone I, fig. 1).—Although it is conceivable that an apical cell may be present at some phase in the embryogeny of *C. revoluta*, as is the case in certain of the Abietineae (Buchholz, 1920), no evidence of the permanent existence of such a cell appears from my investigations on the apices of seedlings and adventitious buds. It is true that certain preparations or individual sections in a series might seem to indicate the existence of a definitive apical cell. For example, in the surface

view of a seedling apex shown in figure 4a, a small triangular cell, with a recent division wall parallel to one of its sides, is apparent. This cell, also shown 8 microns below the surface in figure 4b, might easily be interpreted as a typical apical cell, and its immediate neighboring cells as "segments." Indeed, the cell-net in figure 4a bears a striking resemblance to Dingler's (1882, taf. I, fig. 1) figure of the presumptive apical cell and its recent segments in the shoot apex of a seedling of Ceratozamia. However, surface views of several other seedling apices in C. revoluta showed a highly irregular arrangement of cells and clearly suggest that the cell net depicted in figures 4a-b merely represents a transitory "constellation" in an ever-changing cell pattern. This conclusion is firmly supported by a careful examination of thin serial longisections through about 40 shoot apices. Sections cut in this plane show that no fixed or regular scheme of segmentation characterizes the terminal cells in the median region of the apex. Occasionally, a cell may be found in a median longisection which suggests in its form a definitive apical cell (fig. 8). However, there is no evidence that such a cell is "permanent" in character or regular in plane of cleavage. Furthermore, serial sections clearly demonstrate that essentially similar wedge-shaped cells may arise distal to the median plane by the oblique and unequal division of surface cells (fig. 2a-b, 5a-b, 9a, 11). More frequently, the geometrical apex of the terminal meristem is occupied by a relatively large prismatic cell, around which are grouped its most recent derivatives. In some preparations, the lateral derivatives of this prismatic "initial" have divided periclinally, thus producing a comparatively regular group of related cells (pl. I, fig. 2; fig. 3b-c, 5b. 6b-d). In other apices, no such regular segmentation obtains, and it is evident that the sequence of anticlinal, periclinal, and oblique divisions in the presumptive initial and its derivatives fluctuates within wide limits (pl. I, fig. 5, 6; fig. 2a-b, 7e-f, 10a-b). A similar condition is apparently also characteristic of the seedling apex of Zamia floridana, although no intensive study of this species has been made (fig. 13).

In view of the wide variations just described in respect to the shape and planes of division of the terminal cells in the shoot apex, it is impossible to

the extreme left of the figure.  $\times 36.5$ .—Fig. 4. The central and peripheral tissue zones of fig. 3 at higher magnification ( $\times 217.5$ ). Note the thick walls, large nuclei and collapsed lightly-stained cytoplasm of the large central cells. For emphasis and clarity, this section is also shown as text fig. 4g.—Fig. 5. Longisection through shoot apex of a seedling of C. revoluta to illustrate contrast between central and peripheral tissue and the method of cataphyll initiation (right flank). Observe the notable radial depth of the cells of the apical initial group, one of which has experienced a typical T-division. This section is 16 microns distal to text fig. 2a.  $\times 217.5$ .—Fig. 6. Approximately median section of the shoot apex of an adventitious bud from the trunk of a large specimen of C. revoluta. This massive cone (maximum width 460 microns, maximum height 276 microns) illustrates the structure typical of slowly-growing shoots. Note that the central tissue is well defined and consists of prominent but irregular cell groups, the "mother" walls of which are irregularly thickened especially at the corners. A metaphase is visible in a central cell near the base of the figure. Periclines are evident in many of the surface cells of this apex.  $\times 150$ .—Fig. 7. Approximately median longisection of the shoot apex of Abies venusta. The peripheral tissue (note telophase at upper right) consists of several "layers" of deeply-stained cells which surround the prominent core of central tissue. The darkly-stained material in the central cells presumably represents tannin. Contrast the comparatively orderly arrangement of the cells in the peripheral and central tissue with their "homologues" in Cycas (fig. 2, 5, 6).  $\times 217.5$ .

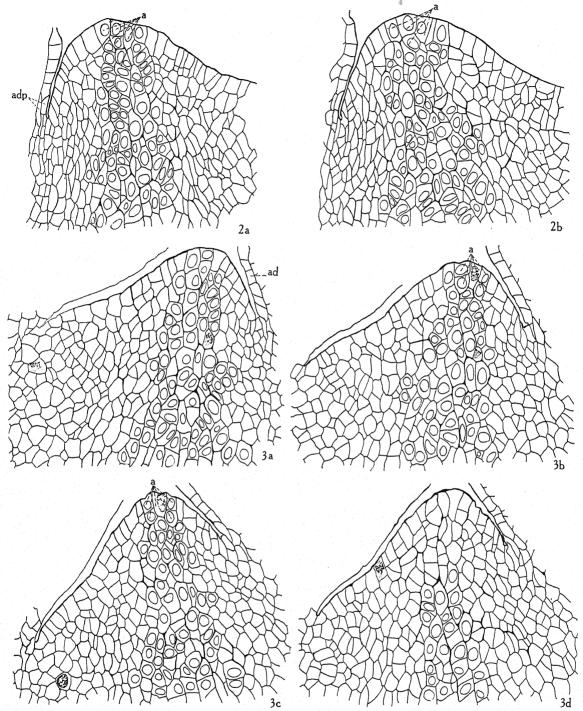

Fig. 2-3. Longisections of shoot apices of seedlings of *C. revoluta*. In these and all following figures, the extent of the central tissue (zone II, fig. 1) is indicated by nucleated cells, while the cells of the peripheral tissue (zone III, fig. 1) are shown in outline only. In the presumptive median section or sections, nuclei are also represented in the cells and immediate derivatives of the apical initial group (zone I, fig. 1). Localized wall-thickenings in all regions are demarcated by heavy outlines, surface views of primary pit-fields by stippling. Fig. 2a-b, adjacent sections through median region of apex illustrating origin of central and peripheral tissue from the apical initial group. Note especially the two large cells in the central tissue in fig. 2b. Fig. 5, pl. I represents a section from the same apex 16 microns distal to fig. 2a. Fig. 3a-c, adjacent sections through median region of another apex, showing an unusually regular segmentation of the cells of the apical initial group; fig. 3d 12 microns distal to fig. 3c. Legend: a, cells of apical initial group; ad, adaxial surface of cataphyll primordium; adp, periclinal division of adaxial surface cells of cataphyll primordium. All figures ×217.5.

determine the theoretical number of "permanent" initial cells. In my opinion, the evidence points to the conclusion that a varying number of fundamentally similar cells act in unison as an apical initial

group from which arise the peripheral and central tissue-zones of the apex. It also seems justifiable to conclude that the growth and division of cells in the apical initial group are not primary and "deter-

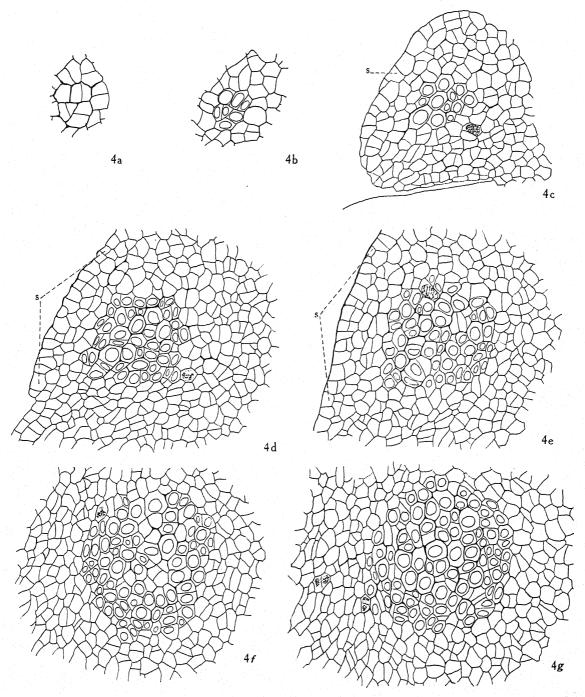

Fig. 4a-g. Transections through shoot apex of seedling of C. revoluta.—Fig. 4a. Surface view of cells of apical initial group.—Fig. 4b-4g, sections at levels respectively of 8, 56, 80, 112, 160, and 176 microns below fig. 4a. Note that while the majority of cells in the central tissue are highly variable in size and arrangement, a marked tendency to radial alignment is shown at the margins of this zone in relation to the propagation of the inner portion of the peripheral tissue. The marked contrast between central and peripheral tissue is shown for fig. 4g in pl. I, fig. 4. Legend: a, apical initial group; s, surface cells of flank of shoot apex.  $\times 217.5$ .

minative" processes but instead are subordinated to the general distribution of growth in the shoot apex as a whole.

THE CENTRAL TISSUE (zone II, fig. 1).—The zone of central tissue has the form of a broad-based cone

which terminates in the uppermost median region of the shoot apex. Since precise orientation of bud material on the block carrier of the microtome is virtually impossible, many series were obtained in this investigation which were obviously oblique to

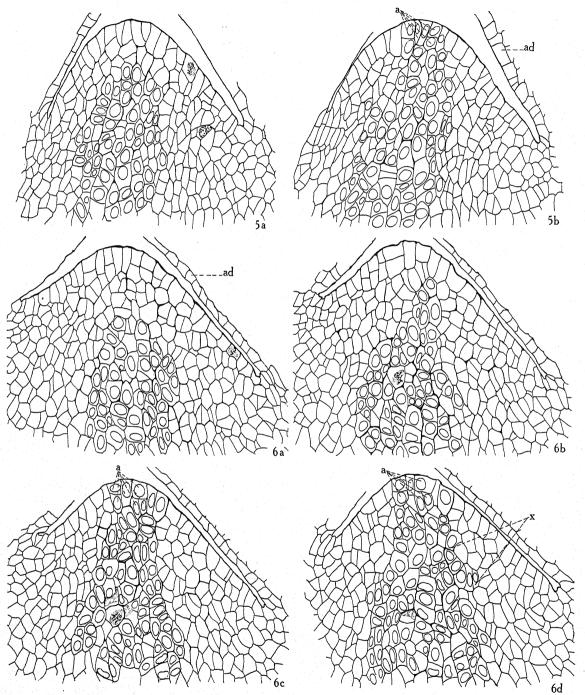

Fig. 5-6.—Fig. 5a-b, longisections through shoot apices of seedlings of *C. revoluta*; fig. 5b, approximately median and 30 microns distal to fig. 5a. Fig. 6a-d, longisections through another apex. Fig. 6c-d, median; fig. 6a-b, respectively 36 and 12 microns distal to fig. 6d. Note surface views of primary pit-fields in fig. 6c-d and origin of group of peripheral cells from edge of central tissue in fig. 6d at x. Fig. 2, pl. I represents the section following fig. 6d in the same apex. Legend: a, apical initial group; ad, adaxial surface of cataphyll primordium. All figures ×217.5.

the median axis of the apex. Consequently, the sections used for illustrations in this paper were selected only after a careful examination of a wide series of preparations. The determination of the "median" longitudinal section or sections was based upon (1) the symmetry and contour of the sections at either side and (2) the relative length and breadth of the zone of central tissue. These criteria will become evident from an examination of figures 6 and 7, which show the change in form and proportion of the central tissue at progressive levels in two shoot tips. The conical form of the zone of central tissue is likewise clearly illustrated by the series of transverse sections shown in figure 4.

The central tissue of the shoot apex of both seedlings and adventitious buds arises from a group of subterminal "mother cells" which represent the inner derivatives of the cells of the apical initial group (pl. I, fig. 2, 5, 6; fig. 2a-b, 3a-c, 5b, 6c-d, 10a-b). There apparently is no orderly plan of growth or division in these mother cells. In some apices, repeated periclinal divisions (with respect to the geometrical apex) result in short rather welldefined groups or files of cells which can be clearly traced to the apical initial group (fig. 2a, 3a-b, 7e-f, 10a). Other preparations, however, show an exceedingly variable pattern resulting from the enlargement and division in many planes of the mother cells (pl. I, fig. 2, 5; fig. 5b, 6c-d). This is particularly true of the apex of adventitious buds where the subterminal mother cells as seen in both transverse and longitudinal section are arranged in complex cell-groups suggestive of Schüepp's (1926, p. 16-17) "Massiges Meristem" (pl. I, fig. 6).

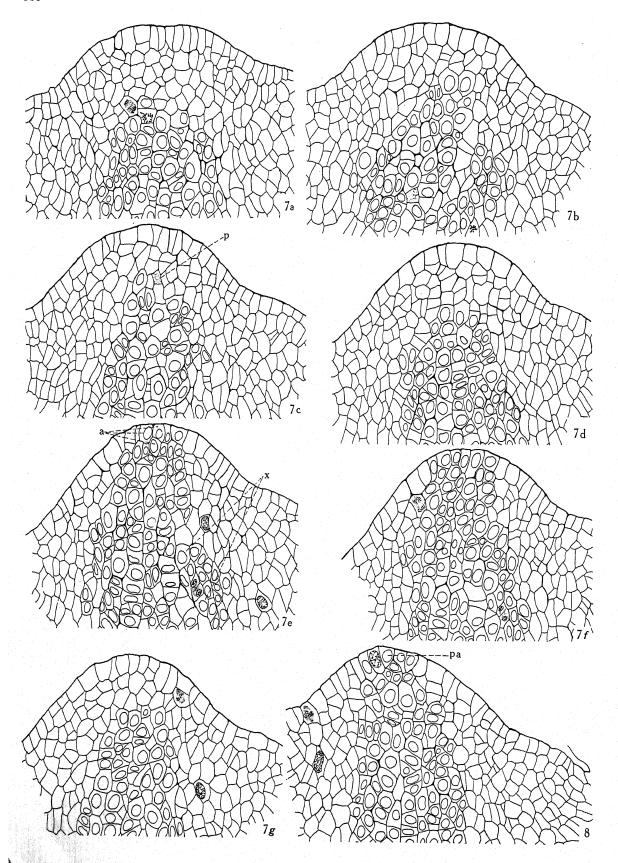

The gradual basipital differentiation of the central tissue is marked by the relatively enormous increase in size of many cells and the subsequent formation from them of irregular cell groups. Unquestionably this is one of the fundamental processes characteristic of the central tissue and is responsible for the highly variable size and arrangement of cells which distinguishes this zone. Although no statistical study of cell size was made, a few representative measurements indicative of the order of magnitude may be of interest. For example, the dimensions (i.e., length × width in microns) of the two elongated upper and lower central cells at the upper left of figure 2b are respectively 44 imes 16.5 and 40.7 imes 13.2. Other prominently enlarged central cells, more nearly "isodiametric" in form, vary from 25 to 35 microns in maximum length and width. The volume of such cells cannot be accurately determined but clearly approaches the order of 7000-8000 cubic microns.

As stated above, the enlargement of a given central cell is eventually followed by a series of divisions, resulting in the production of a genetically-related cell group. If the direction of enlargement is more or less strictly vertical with respect to the longitudinal axis of the shoot apex, filament-like series of cells are produced which collectively re-

semble a typical rib meristem (Schüepp, 1926). This type of growth and cell formation is particularly obvious in the lower region of the central tissue but may occur, in varying degrees, at any level in the zone (pl. I, fig. 2, 5; fig. 2, 3, 5-10, 12). It clearly reflects the notable emphasis on anticlinal growth typical of the central tissue zone (cf. fig. 1). At any point in the central tissue, however, cells may expand more or less uniformly in all directions. The sequence of anticlinal, periclinal and oblique divisions in such cells is highly variable, and the exact origin of the resulting cell-groups is hence difficult to determine (cf. especially fig. 3a-b, 4d-f, 6b-d, 10a-b). This type of cell behavior indicates that irregular radial expansion accompanies the vertical extension of the cone of central tissue (fig. 1). Additional evidence of this complex interrelationship is shown by the frequent radial enlargement of cells at the edge of the central tissue and the production of cell groups which become incorporated in the inner portions of the peripheral tissue (pl. I, fig. 2, 4, 5; fig. 6d, 7e, cell-groups labelled X). Under such circumstances, it should be apparent that the "limits" between the central and peripheral tissue zones can be only approximately established in the shoot apex of seedlings. These zones clearly have no rigid histological boundaries but on the contrary are mutually interdependent. A similar relationship is likewise shown in the massive apices of adventitious buds (pl. I, fig. 6).

Aside from the mode of growth and cell formation just described, several additional characteristics help to demarcate the cells of the central tissue. One of the most obvious of these features is the conspicuous plasmolysis of many of the protoplasts as contrasted with the more satisfactory fixation of the cells of the adjacent peripheral tissue (pl. I, fig. 1-5). It seems reasonable to conclude that the marked collapse of the lightly-stained cytoplasm in the central cells is correlated with their highlyvacuolated state during the phase of enlargement. In order to test this assumption, a large number of seedlings are now being grown so that the effects of a wide range of killing and fixation reagents may be determined. It is also hoped that observations on living meristem, with the aid of vital stains, may prove feasible.

Lastly, attention must be called to the notable development of irregular wall-thickenings in the cells of the central tissue. Although similar thickenings occur in other regions of the meristem, they are more frequent and impressive in this zone. This appears particularly true of the apex of adventitious buds (pl. I, fig. 6). As seen in section view, the thickened areas are most prominent at the corners of a cell from which points they taper gradually or abruptly toward the lateral walls (fig. 2–12). When a cell of this type divides, the new walls are thin and delicate and hence easily distinguishable from the thicker lateral walls of the original "mother cell." This contrast in wall thickness obviously

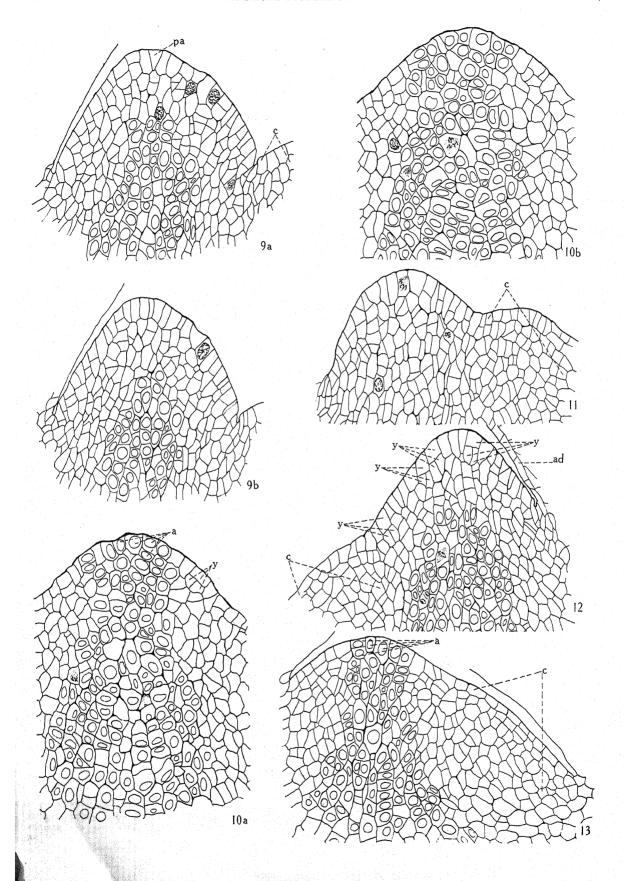

facilitates the determination of cell lineages within the central tissue. When observed in surface view, the lateral wall of a central cell typically appears as an irregular reticulum (fig. 6c-d; 7c, 10a). The unthickened areas in this meshwork presumably represent "primary pit-fields" from which the abundant simple pits, typical of the walls of the pith cells, take their origin. With the generous aid of Professor T. E. Rawlins of the Department of Plant Pathology, University of California, a brief study has been made to determine the structure and chemical nature of the thickened areas of the walls of cells in the central tissue. Our observations were made upon unstained longisections of the shoot apex of an adventitious bud of C. revoluta. When observed between crossed nicols, the outer layer of the lateral and corner thickenings was strongly birefringent or anisotropic, while the inner portion of the wall appeared isotropic or dark. After treating the sections with zinc-chlor-iodide followed by 65 per cent H<sub>2</sub>SO<sub>4</sub>, the lateral walls and corner thickenings in the meristem proper swelled and showed the blue color typical of cellulose. Using this technique, the primary pit-fields appeared as small light areas in the midst of a thicker blue reticulum. In the young pith cells, derived from the central tissue, the blue color was confined to the outer layer of the wall, the inner portion remaining colorless. Presumably then, the cell wall consists of an outer region composed of cellulose, while the inner portion may be pectic material or a combination of pectic material and non-pectic hemicellulose. These studies are to be regarded as exploratory in character, however, and no attempt can be made at this point to determine the limits between "primary wall" and "intercellular substance." A more detailed investigation of this problem is contemplated for the future.

THE PERIPHERAL TISSUE (zone III, fig. 1).—As seen in longitudinal section, this external tissuezone diverges from the apical initial group as a mantle of deeply-stained cells entirely surrounding the core of central tissue (pl. I, fig. 2, 4, 5; fig. 4c-g). Reference to figures 2-12 will demonstrate that the cells of the peripheral tissue show no evidence of a definite stratification at any point in the seedling apex. This is true even of the superficial cells which collectively bear no resemblance in their growth and planes of division to a "dermatogen" or 'tunica" layer. The present investigation therefore supports the earlier observations of Strasburger (1872), Warming (1877), and Bower (1884), all of whom emphasized that a typical "dermatogen" does not occur in the shoot tips of cycads. Under such circumstances, Chamberlain's (1935, p. 147, fig. 162) statement that in the shoot apex of the embryo of Dioon "periclines show that the dermatogen is not yet fully differentiated" (italics mine) seems vague and misleading. On the contrary, it seems extremely improbable to me that a dermatogen, in the sense originally defined by Hanstein (1868), is ever "differentiated" at any stage in the growth of the shoot apex in cycads (pl. I, fig. 6). Further comparative studies on other genera might provide exceptions to this conclusion. However, it seems significant that fundamental agreement with the situation in C. revoluta was noted in the apex of a vigorous expanding adventitious bud of C. circinalis L. as well as in the embryo, seedling, and adult plant of Zamia floridana (cf. fig. 13).

Aside from the irregular contributions made from the marginal cells of the central tissue-zone (fig. 6d, 7e, x), the bulk of the peripheral tissue clearly originates from the anticlinal derivatives of the apical initial group. These derivatives often attain a length of 25-30 microns and in their marked radial depth and lightly-stained appearance resemble "segments" of a prismatic apical cell (pl. I, fig. 2, 5; fig. 2a-b, 5b, 6c-d). As might be expected from their shape, these cells eventually divide periclinally, but the succeeding planes of division in the daughter cells are so rapid and variable that it becomes difficult to determine cell lineages with any confidence. It is evident, however, that the outer daughter cells produced by these earliest divisions retain a remarkable capacity for growth and cell formation throughout the further development of the peripheral tissue. The sequence of anticlinal, periclinal, and oblique divisions in these surface cells follows no fixed plan, and the radially-aligned cell groups are correspondingly variable in size and shape. Commonly, the periclinal division of a surface cell is followed by the anticlinal division of one or both of the daughter cells (fig. 5a, 6a, 7g). If the outer daughter cell divides first, a cell trio results in which the new intersecting walls have the form of a T. More frequently, however, the inner daughter cell is the first to divide. Such T-divisions are apparently very characteristic of C. revoluta and may occur at any point in the surface of the peripheral tissue (fig. 2a, 7f-g, 10a at y, 12 at y). In other instances, the original periclinal division of the surface cell may be followed by one or more divisions in the same plane in either or both of the daughter cells. This type of activity is sooner or later accompanied by anticlinal or oblique divisions in various cells of the group and results in a very complex cell net. Various stages in the process may be followed by comparing figures 3d and 8 with figures 9a-b.

It should be apparent from this description of cell formation that the peripheral tissue constitutes

Fig. 7-8. Longisections through shoot apices of seedlings of C. revoluta. Fig. 7a-g, series of sections illustrating the structure growth and extent of central and peripheral tissue at various levels in an apex. Fig. 7e-f, adjacent median sections showing irregular apical initial group at a; fig. 7a-d, respectively 60, 36, 24, and 12 microns at one side of fig. 7e. Fig. 7g, 18 microns at other side of fig. 7e. Note particularly the active propagation of peripheral tissue from the edge of the central tissue at a in fig. 7e-f and the primary pit-fields (p) in fig. 7c. Fig. 8, approximately median section of another apex illustrating a pseudoapical cell (pa) and a clear demarcation between central and peripheral tissue zones. All figures  $\times 217.5$ 

a zone typified by active centrifugal growth in thickness (fig. 1). This process reaches a maximum at the base of the shoot apex and is one of the factors which appears to determine the emergence of localized "folds" or leaf primordia. Although no effort has been made in this study to follow in detail the early development of either the foliage leaf or cataphyll, certain aspects of this problem deserve brief mention at this point. Firstly, the initiation, at least of the cataphyll, is evidenced by an acceleration of growth and division in the inner portion of the peripheral tissue accompanied by numerous periclines in the surface cells (fig. 11, 13). In this respect my observations are in general agreement with the statements of Strasburger (1872) and Warming (1877). But the emphasis of these investigators and of Bower (1884) on the early demarcation of a "dermatogen" layer in the young leaf is not supported by my study. An examination of radial longisections through a number of cataphyll primordia clearly showed that periclinal divisions occur abundantly in the surface cells, particularly near the adaxial basal region (fig. 2a-b). A thorough study of the significance of periclinal divisions, with particular reference to the processes of apical and marginal growth, is planned for the future. In addition, light may be thrown upon the vexed question (Thiessen, 1908) of the origin of the procambium and the development of the complex girdling leaftraces typical of cycads (cf. pl. I, fig. 1, 3).

Discussion.—The idea is widely held today that the cycads are an isolated and extremely primitive group of plants which show no obvious connection with either the ferns, other gymnosperms, or the angiosperms. Schuster (1932, p. 47) for example holds the opinion that the cycads are "the most primitive group in the Siphonogams without phyletic relationship to a definite group of higher plants." A somewhat similar viewpoint is maintained by Chamberlain (1935, p. 161), who states that the living cycads "are the last of their race, restricted in geographical distribution, restricted in number, and struggling for their very existence." If these views are correct, and there is considerable morphological evidence in their favor, no direct phylogenetic comparison can be made between the structure of the shoot apex in cycads and that of other living vascular plants. Furthermore, any effort at comparison must be restricted largely to the situation in Cycas revoluta, since previous studies on Zamia (Hofmeister, 1857), Ceratozamia (Dingler, 1882; Warming, 1877), and other species of Cycas (Warming, 1877; Bower, 1884) are both vague and contradictory. Under these circumstances, the following anatomical comparison is admittedly provisional in character. Its chief values may consist (1) in directing attention to the value of meristem structure in problems of comparative morphology and (2) in indicating the need for extensive studies on the shoot apex of all the major groups of the Tracheophyta.

A comparison between the structure of the shoot apex in cycads and Ginkgo should be of particular interest in view of certain resemblances in reproduction and embryogeny between these primitive gymnosperms (Chamberlain, 1920, p. 149). Although Ginkgo agrees with C. revoluta in the fact that all tissues of the apex originate from a single apical initial group, the zonal structure of the terminal meristem in the two genera is quite dissimilar. This is shown in the first place by the contrast in structure and growth of the median axial region of the shoot apex. In Ginkgo, as I have recently described in detail (Foster, 1938), the upper median region of the apex consists of a clearly-defined cupshaped zone of enlarged, slowly-dividing "central mother cells." The formation of the rib-meristem from the base of this cup involves a rapid and abrupt transition to a zone of much smaller, more deeplystained and more actively-dividing cells. Depending upon whether a "spur" or "long" shoot is examined, there is a short or prolonged period of growth in the rib meristem which ultimately differentiates into the pith of the shoot axis (cf. Foster, 1938, fig. 1-2 and pl. 25, 26, 27). In marked contrast, there is no comparable demarcation of successive vertical zones in the shoot apex of C. revoluta. Here, a prominent but continuous core of central tissue arises from a few subterminal cells and produces basally the broad pith of the shoot axis (pl. I, fig. 1). In other words, there is no sharp boundary in Cycas between an upper "mother cell region" and a lower zone of rib meristem. As I have already shown, more or less prominent vertical series of cells, resembling rib meristem, may form at any level in the central tissue, although they are most obvious in the basal portion (pl. I, fig. 2, 5, 6; fig. 2, 3, 5-10, 12). A second interesting contrast between Cycas and Ginkgo

Fig. 9-13.—Fig. 9-12. Longisections through shoot apices of seedlings of C. revoluta. Fig. 9a-b, adjacent sections slightly distal to median plane of apex, illustrating centrifugal growth in thickness typical of peripheral tissue. Note prominent pseudoapical cell (pa) and the irregular sequence of periclines and anticlines in its apparent surface derivatives in fig. 9a.—Fig. 10a-b, adjacent median sections of an unusually large apex, illustrating the origin and active growth of the massive central tissue. Note particularly the irregular files of rib-meristem in the lower portion of these sections. A typical T-division in a surface cell is shown at y in fig. 10a.—Fig. 11, non-median section of another apex illustrating the active periclinal division of surface cells during cataphyll initiation. Note the obliquely oriented metaphase in a "terminal" surface cell.—Fig. 12, non-median section of another apex illustrating typical structure and growth of the peripheral tissue. The cell-groups labelled y have arisen by T-divisions. Note smaller cell size in central tissue as compared with fig. 10a-b.—Fig. 13. Approximately median section through the shoot apex of a seedling of Zamia floridana. Note the large size of several of the cells in the central tissue, the active periclinal division of surface cells and the early phases of cataphyll initiation on the right flank of the apex. Legend: a, cells of apical initial group; ad, adaxial surface cells of cataphyll primordium; c, cataphyll initial; pa, pseudoapical cell; y, cell groups originating by T-divisions. All figures  $\times 217.5$ .

is provided by the structure and mode of growth of the peripheral tissue of the apex. In both genera, this zone exhibits marked "embryonic" characters as shown by the numerous mitoses and the deeplystained appearance of the cells. Aside from this resemblance, cell growth and cell arrangement are noticeably different, particularly in respect to the behavior of the superficial cells. In Ginkgo, these cells tend to divide frequently in an anticlinal plane and hence appear collectively as a more or less discrete "surface layer" (Foster, 1938, fig. 5-12). On the other hand, the surface cells of the apex of C. revoluta vary so greatly in their size, shape, and successive planes of division that it is impossible to recognize any regularity of arrangement. This contrast appears to reflect a basic difference in the general distribution of growth throughout the peripheral tissue of Cycas and Ginkgo. In the latter, surface growth accompanied by a tendency toward a stratification of cells is characteristic (Foster, 1938, fig. 3), whereas in Cycas, centrifugal growth in thickness results in a highly variable pattern of cells (fig. 1).

From a comparative standpoint, the terminal meristems of Ginkgo and Cycas revoluta represent two well-defined "types" which permit of no close comparison with the shoot apices of other living vascular plants. Probably the closest resemblance to Cycas is shown by certain of the Abietineae. A median longisection through the apical cone of a vigorous expanding shoot of Abies venusta (Dougl.) K. Koch. will serve as an example (pl. I, fig. 7). It is evident from this photomicrograph that a central core of vacuolating, tannin-filled cells is surrounded by a peripheral zone composed of three or four "layers" of small densely-cytoplasmic cells. These two histological regions obviously show a noticeable similarity respectively to the peripheral and central tissue-zones in the shoot tip of C. revoluta (pl. I, fig. 2, 5, 6). Differences nevertheless will soon be apparent if the size and particularly the arrangement of the cells in the two zones of Cycas and Abies are compared. Clearly, the cells of the peripheral tissue in Abies are more or less definitely stratified as contrasted with the irregular cell pattern in the presumably equivalent zone in Cycas. Furthermore, the boundary between the central and peripheral tissue zones is "sharp" in Abies, while, as I have previously emphasized, only approximate limits can be set between these zones in C. revoluta. This latter difference appears to be correlated with a greater regularity in the direction of growth and plane of division of the central tissue in Abies which exhibits more uniformly the general features typical of rib meristem. If, as I have previously suggested (Foster, 1938, p. 553), the two major tissue regions in the shoot apex of Abies and other conifers (cf. Koch, 1891; Korody, 1937) represent a "transitional stage" in the evolution of the zonation characteristic of the angiosperms, the situation in Cycas acquires considerable interest. That the peripheral tissue in this species should be regarded as typify-

ing an extremely "primitive stage" in the evolution of the tunica zone (Schmidt, 1924) in angiosperms might readily be questioned from the standpoint of current phylogenetic theory. The morphological interest of the present study on Cycas is that it gives us, to some degree at least, an idea of the nature of terminal growth in one of the most ancient types of existing seed plants. Whether the growth and associated cellular organization of this shoot apex will eventually aid in the interpretation of the apical meristems of more advanced seed plants or whether these features are unique and peculiar to cycads are problems which must await further comparative study for their solution.

#### SUMMARY

A detailed study has been made of the structure and growth of the shoot apex of seedlings and adventitious buds of *Cycas revoluta* Thunb. The anatomy of the terminal meristem of the seedling of *Zamia floridana* A.DC. is also briefly described.

No evidence has been found of the existence of a "permanent" apical cell. On the contrary, all the tissue of the shoot apex in both Cycas and Zamia can be traced in ultimate origin to the activity of a single group of apical initial cells which divide anticlinally, periclinally, and obliquely without regular sequence. Although a large prismatic cell may appear to dominate for a time in this initial group, its individuality is eventually submerged as a result of irregular and variable planes of segmentation.

The tissue derived from the apical initial group in Cycas is not uniform in structure but is segregated into two more or less clearly demarcated zones: (1) a prominent conical zone of central tissue which is completely surrounded by a mantle of deeply-stained peripheral tissue. These zones are characterized by significant differences in the growth, planes of division, arrangement, and relative size of the component cells.

Pronounced cell-enlargement, followed by the formation of well-defined cell groups, are the distinctive histogenetic features of the central tissue in Cycas. When the direction of growth and enlargement of a given "mother cell" is approximately vertical, a linear series of daughter cells is produced. This type of cell enlargement and cell formation is particularly evident in the lower region of the central tissue, where the irregular filamentous cell groups collectively resemble a rib meristem. At any position in the central tissue, however, cells may enlarge more or less uniformly in all directions, and the resulting cell lineages are correspondingly difficult to interpret. The walls of the central cells, especially at the corners, are often prominently thickened. A preliminary study of these thickened areas in an adventitious bud of C. revoluta between crossed nicols showed that the outer lamellae are strongly birefringent (i.e., anisotropic), while the inner region appears dark (i.e., isotropic). When treated with chlor-zinc-iodide followed by 65 per

cent H2SO4, the outer portion of the thickenings gave the blue color typical of cellulose.

The peripheral tissue of the apex in Cycas is composed of smaller cells characterized by their "embryonic" appearance (i.e., absence of impressive enlargement) and frequent divisions. Judging from the cell net and the orientation of mitotic figures, the prevailing direction of growth in this tissue-zone is centrifugal. The surface cells retain a marked capacity for continued growth and division; collectively, they do not resemble in arrangement or plane of division a "dermatogen." Periclinal divisions in these surface cells are followed usually by the anticlinal division of one or both of the daughter cells. Often several successive periclinal divisions, followed by anticlines or obliquities in the derivatives, may occur. The radially-aligned cell groups thus formed are complex in structure and variable in size. Foliar structures are initiated at the base of the shoot apex by a localized acceleration of growth and cell division in the peripheral tissue, accompanied by frequent periclines in the surface cells. Periclines are also numerous in the adaxial surface cells of the cataphyll primordia, which, at least during early ontogeny, do not possess a typical dermatogen.

An anatomical comparison of the shoot apices of Cycas revoluta and Ginkgo biloba reveals few points of resemblance, and the terminal meristems of these forms are regarded as distinct "types" among living vascular plants. The closest structural resemblance with Cycas is exhibited by certain conifers such as Abies venusta.

# THE COLOR OF MYXOMYCETE PLASMODIA 1

Paul E. Kambly

ALTHOUGH THERE is considerable evidence in the literature on myxomycetes that plasmodia of some species exhibit consistency of color on different substrata, there are also many conflicting reports concerning the plasmodial color of other forms. The Lister monograph (1925) and, to a much less extent, Macbride and Martin (1934) use plasmodial color as a taxonomic character. Pinov (1908) postulated sexual dimorphism in Didymium nigripes on the basis of the occurrence of differently colored plasmodia. Skupienski (1934) reported a thermophilic race of Didymium xanthopus which is distinguishable, in part, by a white plasmodium. A. Lister (1888) was one of the first to describe a color change due to the ingestion of colored particles by a plasmodium. Cadman (1931) and Gray (1938) mention the same phenomenon. Color changes due to bacterial associates have been described by Pinov (1903) (1915), Skupienski (1920), and Raper (1937). If plasmodial color is to hold any place as a taxonomic character or as an aid in distinguishing strains and races, information concerning the factors which influence color is essential. This paper reports observations on plasmodia grown in the laboratory, with particular reference to color variations caused by certain bacterial associates.

MATERIALS AND METHODS.—The plasmodia used in the experiments described were collected in the field or obtained from spore sowings. Both sclerotia and active plasmodia were collected and placed in moist chambers in the laboratory. Cultures obtained from spores were started by sowing spores in distilled water in Syracuse watch glasses. The watch glasses were left on the laboratory table and no precautions taken to protect the swarm-cells from light. They were kept covered by another watch glass to reduce the risk of contamination by another myxomycete. The spores were observed from time to time with either a low power objective or a water immersion lens and after germination were transferred to nutrient agar with a clean pipette. The chief advantage of sowing spores in water rather than directly on the nutrient agar is that viability of the spores can be determined in water and that failure to obtain plasmodia because of non-viable spores may be ascertained. A further advantage is that growth time on agar is shortened, and thus the amount of contamination is reduced. A 2.5 per cent carrot decoction agar proved to be a very satisfactory nutrient medium for obtaining plasmodia from spores. The amount of available nutrient material in this medium seemed to be small enough to discourage excessive mold growth and yet great enough to support the growth of a bacterial film over the surface of the agar. This nutrient agar was pre-

<sup>1</sup> Received for publication April 10, 1939.

The writer expresses his appreciation to Prof. G. W. Martin for suggestions and criticisms during the progress of the work and in the preparation of this paper.

pared by boiling the carrots for one and a half to two hours. Then agar was added, the carrot particles were removed by filtration, the pH adjusted to approximately 7, and the medium was tubed and autoclayed.

Serratia marcescens, Chromobacterium violaceum, and Sarcina lutea, grown on beef-peptone agar, and Phytomonas fascians<sup>2</sup> grown on potato-dextrose agar were used as plasmodial associates. These organisms produced red, violet, yellow, and cadmium yellow pigments, respectively. In experiments performed with plasmodia collected in the field the plasmodia were first obtained in active condition upon plain agar plates and the bacteria added as a suspension in distilled water. Plasmodia obtained from spore sowings were kept on nutrient agar, and the bacterial suspensions were added. All cultures were maintained in the diffuse light of the laboratory at room temperatures which varied from 20°C.

The arrangement and nomenclature which follows is that of Machride and Martin.

DETAILED OBSERVATIONS.—Records of several Fuligo septica plasmodia collected in the field, indicate a variability in plasmodial color in this species. These plasmodia fruited and were positively identified. One specimen growing on apple bark had an ocher-gray plasmodium when collected, but transplants to plain agar plates yielded both white and yellow plasmodia. The yellow forms tended to become white in the laboratory. A different specimen produced only white transplants. Another plasmodium growing on very rotten wood was bright yellow when collected. Three days later part of this collection on plain agar was snow white. On the same day one culture plate containing wood on plain agar showed a greenish yellow plasmodium, and part of the same plasmodium in another Petri dish on plain agar was light yellow and "frothy." Six days later this light yellow plasmodium had fruited. Transplants of all three collections were subjected to suspensions of Serratia marcescens and always became pink within a few hours. None of these completed its life cycle, and sclerotia were formed in every case. Suspensions of Sarcina lutea produced no noticeable color change but the plasmodia remained active slightly longer than with Serratia. White plasmodia of Fuligo septica have been obtained from spore sowings on 2.5 per cent corn agar, but none grew to large size nor completed its life cycle in culture.

Physarum polycephalum.—Since it was possible to collect the plasmodia of this species in the field, no attempts were made to obtain them from spore sowings. Several plasmodia found growing on old

<sup>2</sup> Tilford, P. E. 1936. Fasciation of sweet peas caused by *Phytomonas fascians* n. sp. Jour. Agric. Res. 53: 383-394. Culture obtained from Dr. E. M. Hildebrand of Cornell University. hymenophores of *Pleurotus* were all deep yellow. Three different plasmodia collected from rotten logs were definitely greenish yellow. Transplants of these plasmodia to plain agar became orange to redorange within a few hours after a suspension of *Serratia marcescens* was added. In one case a transplant from a yellow plasmodium formed sporangia while associated with the red bacteria. The hypothallus and stalks of these fructifications were red, in contrast with the typical pale yellow of the corresponding parts of sporangia formed on plain agar without bacteria. Suspensions of *Sarcina lutea*, *Chromobacterium violaceum*, and *Phytomonas fascians* neither stimulated growth nor caused changes in color.

Physarum compressum.—Grav reported the cultivation of this species on corn decoction agar, but he experienced difficulty in maintaining transplants. A 2.5 per cent carrot agar proved to be an excellent nutrient medium for the plasmodia obtained from spore sowings. Transplants on this medium enlarged rapidly, produced characteristic sporangia, were consistently pearly white, and did not change color before the formation of sporangia. When Serratia marcescens was added to cultures, the plasmodia became pink and continued their growth. Plasmodia associated with Chromobacterium violaceum, Sarcina lutea, and Phytomonas fascians continued growing but did not change in color. Characteristic sporangia were formed with all four species of bacteria. The stipes were ashen in color in all cultures except those which contained Serratia. These were first red and then brown. Both of these colors occur in natural developments of the species.

Physarum bivalve.—The white plasmodia of this species were obtained easily on carrot decoction agar, and typical bilabiate fructifications were formed by most of them. The typical white plasmodia showed a greater tendency to change color than those of most of the species studied. Alternaria contaminants present in some plates caused the plasmodia to become darker in color because of the ingestion of spores. These large muriform spores could be seen under the binocular as they were carried by the streaming protoplasm. This is in contrast with Howard's (1931) observations of Physarum polycephalum which he found did not ingest Alternaria spores. However, since the plasmodial trail was strewn with the spores it is doubtful whether they were a source of food. The addition of a suspension of Serratia marcescens caused the plasmodia to become pink. In a few cases plasmodia associated with Chromobacterium violaceum exhibited a faint violet tinge. Sarcina lutea caused the plasmodia to develop a faint yellow tint. Plasmodia remained white when grown in the presence of Phytomonas fascians.

Physarum didermoides.—Carrot decoction agar promoted some growth of this species, but none of the plasmodia flourished or completed its life history. The plasmodia were white when small but showed a tendency to develop a yellow tint as they

enlarged. Serratia marcescens was the only bacterial associate which caused a change in plasmodial color, and with this species the plasmodia were pink. Chromobacterium violaceum, Sarcina lutea, and Phytomonas fascians did not encourage growth nor affect the color of the plasmodia.

Physarum leucophaeum.—Only one collection of the plasmodium of this species was obtained. It was found growing on the inside of an old hollowed turnip, and the only fructifications obtained were formed on the original turnip substrate. The plasmodium was yellow on the turnip and remained yellow on plain agar. Carrot agar was not a suitable culture medium, causing a rapid bunching of the plasmodia followed by disintegration. Since portions of the original plasmodium did spread out into typical plasmodia on plain agar plates, it was possible to study the effect of the bacterial associates. Serratia marcescens caused the plasmodium to become slightly orange but also resulted in a rapid withdrawal of the protoplasm into the larger veins. After withdrawal the protoplasm did not resume activity and soon deteriorated. Chromobacterium violaceum, Sarcina lutea, and Phytomonas fascians caused no color changes but did affect the plasmodia in the same way as Serratia marcescens.

Physarum sp.—The plasmodia of this form appeared as contaminants on carrot decoction agar on which spores of Enerthenema papillatum had been sown. They were colorless and watery in appearance, and the fructifications formed were anomalous plasmodiocarps. Serratia marcescens caused the plasmodia to become pinkish red. No color changes were evident when plasmodia were associated with Chromobacterium violaceum. Both Sarcina lutea and Phytomonas fascians caused the plasmodia to develop a yellow tint which became more intense as the plasmodia bunched to form fructifications.

Physarella oblonga.—One collection of the plasmodium of this species was made from a rotten log. It was greenish yellow and maintained this color on carrot decoction agar as well as 2.5 per cent corn decoction and 5 per cent hay extract agar. The only sporangia produced in culture formed on plain agar to which small portions of the original wood, bearing part of the plasmodium, had been added. Serratia marcescens added to a plasmodium on plain agar caused it to become reddish orange. Chromobacterium violaceum, Sarcina lutea, and Phytomonas fascians caused the plasmodial portions to bunch quite rapidly. This bunching resulted in an increase of the intensity of the yellow color.

Didymium squamulosum.—The plasmodia of this species were obtained on 5 per cent carrot, 2.5 per cent carrot, 3 per cent hay, and 2.5 per cent corn decoction agars. Young plasmodia were white, but older plasmodia varied. Large plasmodia on carrot decoction agar were reddish brown. Plasmodia creeping over molds were frequently violet-brown to reddish brown because of the ingestion of spores. Characteristic fructifications were formed on carrot agar. Serratia marcescens caused the plasmodia

to become pink. Chromobacterium violaceum, Sarcina lutea, and Phytomonas fascians did not cause any evident color change. None of these plasmodia fruited while associated with the colored bacteria.

Didymium nigripes.—Plasmodia formed on carrot decoction agar were always white when young. Older plasmodia growing on carrot agar often appeared light yellow to carrot colored. This observation agrees with that of Cadman on the same species. Plasmodia associated with Serratia marcescens became pink but did not complete their life histories. Chromobacterium violaceum, Sarcina lutea, and Phytomonas fascians caused no color changes. Plasmodia associated with these species exhibited the same color variations as those grown on carrot agar to which the pigmented bacteria had not been added.

Didymium xanthopus.—Plasmodia of this species were obtained easily on 2.5 per cent carrot agar. On several occasions they appeared as contaminants in cultures of other plasmodia. Young plasmodia were gravish white but soon changed to a carrot color which they maintained until fruiting. Occasionally the color changed to a pinkish fawn just before sporangia began to form. Transplants of plasmodia to fresh carrot decoction plates thrived and formed numerous characteristic sporangia. The stipes of freshly formed sporangia were much lighter in color than the stipes of the collection from which the spores were sown. Several different plasmodia were grown on carrot agar with Serratia marcescens. These became pink to red within a few hours. Sporangia formed by these plasmodia had pink stipes and heads when young. The older heads appeared characteristic for the species, and the stipes became a dark reddish brown in contrast with the lighter color of stipes formed on carrot agar to which no bacteria were added. Plasmodia on carrot decoction agar to which a suspension of Chromobacterium violaceum was added remained carrot colored until fruiting. Sarcina lutea and Phytomonas fascians suspensions caused no color change, but the plasmodia grew extremely well in association with these bacteria. Stipes of the fruiting structures formed in association with Sarcina and Phytomonas were much lighter in color than those formed in association with Serratia and Chromobacterium.

Clastoderma Debaryanum.—This species was collected in the sclerotium stage. Active plasmodia appeared about six weeks after the sclerotia were placed in a moist chamber. These plasmodia were greenish yellow when crawling over plain agar but were deeper yellow to light brown on wood. No fructifications were formed from transplants to nutrient agar unless a piece of the original pine wood was included with the transplant. Most of the scattered sporangia appeared on the wood, but several were formed on the nearby agar. All attempts to obtain plasmodia from spore sowings were unsuccessful. The only reference to the color of the plasmodium of this species other than in Lister's monograph is one by Beardslee (1908). Lister gives the

color as watery white. Beardslee states, "a log was found and kept under observation which seemed to be completely filled with its plasmodium. This appeared at frequent intervals, covering the log with a pale yellow network of plasmodial threads, changing over night to a thick growth of the delicate sporangia." Adding a suspension of Serratia marcescens to the greenish yellow plasmodia on plain agar resulted in orange-colored plasmodia. Chromobacterium violaceum, Sarcina lutea, and Phytomonas fascians caused no noticeable change in color. As was previously stated, these transplants did not finish their life history. In most cases the plasmodia bunched up and disintegrated, but they occasionally formed sclerotia.

Ophiotheca Wrightii.—Plasmodia appeared on leaves in a moist chamber. They varied in color through white, gray, and light brown. The darker colored plasmodia were those growing on the decaying leaves. On plain agar the plasmodia were white. Serratia marcescens caused the white plasmodia on plain agar to become pink and then to clump into a reddish knob. Chromobacterium violaceum, Sarcina lutea, and Phytomonas fascians did not encourage plasmodial growth nor cause changes in color. In each case the plasmodium bunched up into a small mass. The fructifications obtained were all formed on the natural substrate of dead leaves.

Hemitrichia stipitata.—The plasmodium of this species was yellow when collected but varied from light yellow to a marked greenish yellow in the moist chamber. It was active for three months before any sporangia were formed. Transplants to 5 per cent corn decoction agar varied from white to deep yellow. Several plasmodia on 2.5 per cent carrot decoction agar were cream colored. Plasmodia associated with Serratia marcescens became deep orange colored but withdrew into the coarse veins very rapidly and did not resume activity. The same type of bunching was evident after the addition of Chromobacterium violaceum, Sarcina lutea, or Phytomonas fascians.

Unidentified plasmodia.—In addition to the plasmodia of the species listed above, twenty-five other plasmodia collected in the field, but which failed to form fructifications, were used in this study. Two of these were white when collected, eight were yellow, and fifteen were greenish yellow. The greatest variation in color was shown by one of the two white collections. This produced white, yellow, and greenish yellow transplants. The stock plasmodium growing on wood in a moist chamber became greenish vellow and maintained this color for the four months it was actively growing. There was some fluctuation between yellow and greenish yellow in other plasmodia, but in most cases this variation was associated with, and perhaps a result of, bunching or spreading out of the plasmodium. All twenty-five of these plasmodia changed in color on plain agar plates to which suspensions of Serratia marcescens were added. The color varied from pink through orange to red. No color changes were evident in any

case as a result of adding suspensions of Chromo-bacterium violaceum, Sarcina lutea, or Phytomonas

Discussion.—From the above observations, it is evident that the plasmodial color of some species of myxomycetes is extremely variable. The chemical nature of the pigment has not been determined. Zopf (1889) believed that the yellow pigments are identical with the lipochromes of animals. In addition to the lipochromes, each species he studied possessed at least one other pigment which was soluble in water. Solacolu (1932) concluded that pigments extracted from the sporangia of twenty-six species were anthracene derivatives. Seifriz and Zetzman (1935) concluded: "1. The yellow pigment of the slime-mould Physarum polycephalum is an acidalkaline indicator with a color range from deep red orange to bright yellow-green, and a corresponding pH range from 1 to above 8. 2. Within the slimemould the pigment serves as an acid-alkaline indicator and shows the plasmodium to undergo changes ranging from pH 8 when fruiting to pH 1.6 (possibly 1.2) when a sclerotium is formed. 3. The suggestion is made that the yellow pigment of slimemoulds belongs to the group of respiratory ferments known as flavones, lyochromes, or flavins.' On the assumption that pigments are pH indicators, one can readily account for the gradation between yellow and green which many of the plasmodia used in this study exhibited. The suggestion that the vellow pigment is a respiratory ferment offers a further explanation for variations in color from yellow to white. However, there is little experimental evidence to support this latter view.

The color change produced in every case when plasmodia were associated with Serratia marcescens was similar to that described by Raper (1937) for the pseudoplasmodia of Dictyostelium discoideum. The red bacterial pigment is contained within the cells and is not water soluble. The plasmodia used in this study seemed to ingest and digest part of the bacterial cells but evidently could not digest the pigment, which seemed to collect in scattered vacuoles in the plasmodia and was not excreted when the plasmodia fruited. The failure, with two

exceptions, to obtain corresponding effects with Chromobacterium violaceum, Sarcina lutea, and Phytomonas fascians cannot be satisfactorily explained at the present time. Watanabe (1932) found that Sarcina lutea and Chromobacterium violaceum (B. violaceus) were generally a more adequate source of food for plasmodia than Serratia marcescens (B. prodigiosus). His work shows that the bacteria are ingested. The most plausible explanation for lack of coloration seems to be that the bacterial pigments are broken down by the digestive processes in the plasmodia.

#### SUMMARY

Myxomycete plasmodia collected in the field exhibited considerable variation in color when maintained in moist chamber cultures in the laboratory.

Thirty-nine different plasmodia, including those of Fuligo septica, Physarum polycephalum, Physarum compressum, Physarum bivalve, Physarum didermoides, Physarum leucophaeum, Physarella oblonga, Didymium squamulosum, Didymium nigripes, Didymium xanthopus, Clastoderma Debaryanum, Ophiotheca Wrightii, and Hemitrichia stipitata, changed color when associated with Serratia marcescens. With the exception of Physarum bivalve and Physarum sp., none of these plasmodia was visibly affected by either Chromobacterium violaceum or Sarcina lutea. Only the colorless watery plasmodium of Physarum sp. changed color because of association with Phytomonas fascians.

Young sporangia of Physarum polycephalum, Physarum compressum, and Didymium xanthopus formed in association with Serratia marcescens were pink to red.

The laboratory cultivation of Physarum bivalve

is reported for the first time.

The wide variation in color under natural and experimental conditions suggests that the color of a plasmodium is not a good taxonomic character nor a dependable factor in the delimitation of strains or races.

## THE RELATION OF SPECIFICITY OF ORCHID MYCORRHIZAL FUNGITO THE PROBLEM OF SYMBIOSIS $^{\scriptscriptstyle 1}$

John T. Curtis

THE EXISTENCE of a mutually beneficial symbbiosis between orchids and certain filamentous fungi has been inferred for a number of years. Two principal arguments have been offered in support of this symbiotic view, both of them dealing with the relation of the fungi to the germination of the orchid seeds. The main thesis was advanced by Bernard in 1904 and subsequently supported by Burgeff (1909, 1911, 1936), Costantin (1917), and Ramsbottom (1922, 1927). They maintained that orchid seeds would not germinate without the aid of endophytic fungi found in the roots of the orchids. The second argument dealt with an alleged specific relationship between the orchid and the fungus species and was also advanced by Bernard (1909), who claimed that different orchid plants of the same species or the same genus would always harbor the same species of fungus. This view was held as late as 1927, when Ramsbottom stated that "The same fungus is always present in Cattleya roots and is distinguishable in culture, even with the naked eye, from a culture of the fungus from Odontoglossum."

Certain of Bernard's results led him to apply this idea of specificity to the phenomenon of symbiotic germination. He stated that the seeds of one species or genus of orchids would germinate only in the presence of the fungus from that orchid or others of closely related genera.

Other arguments favoring the existence of a mutually beneficial relationship between orchid and fungus are concerned with the effect of the fungus on the developing seedling or the mature plant. Bernard thought that infection of orchid seedlings led to a tuberization or secondary thickening of stems and rhizomes. Other possible benefits that the orchids derive from their fungal symbionts have been advanced by many workers. Most commonly held is the belief that the fungus serves as a means of absorption and conduction of water and nutrients from the substrate to the roots. This is probably a carry-over from early theories as to the function of ectotrophic fungi on the roots of woody plants. Actually the connecting hyphae between root and soil are very rare in the endophytic forms and prob-

<sup>1</sup> Received for publication April 10, 1939.

The author wishes to express his appreciation to the Wisconsin Alumni Research Foundation for a grant-inaid during the summer of 1937.

ably serve only as agents of infection. Early workers thought that the lack of root hairs in many orchids necessitated the postulation of some other absorbing surface. As a matter of fact, all terrestrial orchids are supplied with root hairs and all epiphytic orchids produce them under conditions of sufficient moisture. The lack of root hairs on some roots of epiphytes is a condition peculiar to the velamen-covered aerial roots, and these aerial roots are almost constantly devoid of mycorrhizal fungi.

Other investigators have thought that plants produced asymbiotically were "abnormal" and would not flower in the absence of fungi in their roots. All these theories concerning the obligate nature of symbiosis, except the one concerning specificity, were disproved by Knudson (1930) when he recorded the production of a normal flower on a Laeliocattleya hybrid grown asymbiotically on a sterile mineral nutrient solution lacking carbohydrates.

SEED GERMINATION.—Early practical orchid growers obtained germination of orchid seeds only by sowing them on a compost containing the living parent plant. Link (1840) was the first to demonstrate that orchid roots may contain an endophytic fungus. This root infection was shown to be fairly widespread by Wahrlich (1886), who found fungi in the roots of more than 500 species of orchids. Bernard (1899) studied very young seedlings (protocorms) of Neottia nidus-avis in nature and found them to harbor a fungus also. From these facts he formulated the hypothesis that the endophytic fungi in the roots could cause germination of the seeds. He proceeded to test this by isolating fungi from orchid roots, growing them in pure culture, and sowing seeds on the pure cultures. He isolated a large number of filamentous fungi from the roots of a Laeliocattleya hybrid and planted seeds of the same hybrid on pure cultures of each of the fungi. With one fungus he obtained good germination. This was proof of his theory that fungi from orchid roots can cause germination of seed. However, Bernard also concluded that because one particular fungus induced germination, it was therefore necessarily the true symbiotic fungus for the orchid in question, and the others were merely contaminating organisms. This conclusion has served as the criterion of a symbiotic orchid fungus—i.e., one which occurs in the roots of an orchid and, in addition, is able to

induce germination of that orchid's seeds. Bernard (1909) and Burgeff (1909) elaborated the early results and concluded that germination can be brought about only by the aid of endophytic fungi belonging to the genus *Rhizoctonia*.

Knudson (1922) showed, in a series of well-executed experiments, that seeds of several representative orchid genera would germinate in the absence of any fungus, if they were provided with soluble sugars. He further showed that the presence of sugar was essential only in the primary stages of germination and that the plants were able to grow normally on a medium containing only the essential mineral elements as soon as the first leaves were formed. He held that the fungus acted through enzymatic action on the starch in the external environment and through an increase of the acidity of the medium

Additional proof that germination of orchid seeds is not dependent on the action of an endophytic fungus was offered in a series of observations on symbiotic germination by fungi other than orchid Rhizoctonias. Burgeff (1909) found that an undetermined brown saprophytic fungus (not a Rhizoctonia) occurring as a contaminant in one of his cultures of Laeliocattleya Acis produced marked stimulation of growth of the seedlings. A white bacterium occurring as a contaminant in other cultures also produced this effect. Knudson recorded the occurrence of germination in asymbiotic cultures contaminated with saprophytic fungi (Penicillium sp.), and most other workers in the field have noted instances where chance organisms have produced marked stimulation of growth. Knudson (1925) tested the extent of this phenomenon by planting Cattleya seeds with an orchid fungus (Rhizoctonia repens). He found that Phytophthora sp., Choanophora sp., and Cucurbitaria sp. all produced germination about as efficiently as did the orchid fungus.

Burgeff (1932) found species of Marasmius, Xerotus, Fomes, and other basidiomycetes to be effective in producing germination of seeds of several Malayan saprophytic orchids. Cappelletti (1935a) obtained good germination of a Cymbidium Cibele hybrid with the fungi Pleurotus, Hypholoma, and Corticium. Derx (1937) pointed out that all regularly accepted orchid endophytes are basidiomycetes. He tested the possibility that other basidiomycetes could cause germination by using Corticium octosporum isolated from garden soil. He found it to cause germination in Laeliocattleya and Dendrobium.

In order further to test the extent of these observations, a series of cultures was set up in the present investigation in which seeds of Cordula insigne were sown with various fungi. Medium Sb of Burgeff (1936) was used as a substrate. After five months the following results were obtained. Good germination occurred with: Ceratostomella sp., Pleurotus ostreatus, and Corticium Catonii; poor germination with Chaetomium bostrychodes and Rhizoctonia repens from Goodyera pubescens; and

no germination with Sporormia leporina, a Chaetomium from Cymbidium, and an unidentified mycorrhizal fungus from Epigaea repens (Phoma sp.?).

The induction of germination by such a wide range of organisms would indicate that there is nothing very exacting about the requirements of the orchids. Perhaps the most significant discovery concerning the physiological relations of fungi and orchids was the observation by Burgeff (1934) and Cappelletti (1935a) that the heat-killed mycelium of an appropriate fungus would cause as good germination as would the living mycelium. This discovery led to the view that the fungus might produce some chemical compound necessary for germination. Burgeff and Cappelletti independently proceeded to identify this growth-promoting substance, whatever it might be. Burgeff isolated from the killed mycelium a substance which he thought related to bios or vitamin B and which stimulated the germination of seeds of the Sarcanthinae in the absence of a living fungus. Cappelletti (1935b), by comparing the effects of the fungi with those of known compounds, concluded that vitamin C was necessary for germination of Cymbidium seeds. Both these workers used seeds which are in some cases difficult to germinate by the non-symbiotic method. Both Vanda and Phalaenopsis (Sarcanthinae) and Cymbidium (Cymbidiinae) will give excellent non-symbiotic germination if the seeds are fresh, but with old seeds the presence of a fungus is necessary for good germination. It is presumably only in these cases that the presence of some growthpromoting substance is necessary.

A summary of these results indicates that orchid seeds will germinate without the aid of any fungus or other micro-organism, provided they are supplied with an adequate mineral nutrient solution and a suitable sugar at the proper hydrogen-ion concentration. If they are planted on an unfavorable medium, such as one containing starch, they need the aid of some fungus or other agency which can change the starch to sugar and can maintain the proper pH. In case this agent is a living organism, it is also necessary that no toxic substance be produced or that the amount of growth of the organism be such as physically not to smother the seeds. This organism need have no relation to the mature orchid plant and is definitely not necessarily the fungus found in the roots of the mature plant. In most cases, fungi fulfilling these requirements are basidiomycetes, but, in several instances, members of the oomycetes and of the ascomycetes have proved capable of inducing germination, and it is probable that many more, especially ascomycetes, will be found which will cause germination.

In nature it is possible that soil fungi capable of changing insoluble complex carbohydrates to simple sugars play a large part in orchid seed germination by providing a suitable food supply in the soil. Burges (1936) has shown that an endophytic fungus isolated from *Orchis incarnata* was able to increase the free, water-soluble carbohydrate content

of previously sterilized fen soil, and a similar action is known to be brought about by such common soil saprophytes as the Mucors and the Penicillia. As Burges points out, "The soil organisms responsible for the decomposition (of insoluble carbohydrates) bear no necessary connection with mycorrhizal fungi, but it is recognized that a fungus may conceivably act in both ways." In any case, there has been no proof that orchid Rhizoctonias alone are responsible for germination in nature.

The above conclusions with reference to the necessity of fungi for germination are applicable only to green, autotrophic orchids. The purely saprophytic forms have been insufficiently studied as yet to offer any firm basis for conclusions.

In the present investigation an effort was made to isolate as many strains or species of mycorrhizal fungi, especially Rhizoctonias, as possible from orchid plants growing in different ecological habitats or different localities in Wisconsin. In addition, isolations were made from orchids secured from Costa Rica and Mexico, for purposes of comparison. The Mexican species were supplied through the kindness of Mr. Eric Ostlund of Cuernavaca, Mexico. Plants of Spiranthes cernua were obtained from Mr. Carl Ramsey, of Dorset, Vermont. Previous work (Curtis, 1937) has shown that one species of orchid may harbor more than one species of fungus, and it was desired further to test the extent of this phenomenon.

The following procedure of isolation was followed throughout. Seemingly healthy roots (those having no apparent sign of decay) were washed with running tap water; all adhering dirt particles were removed by careful brushing. Sample roots were examined microscopically for the presence of an endophytic fungus by means of free-hand sections. The occurrence of fungi could easily be detected by the presence of tangled knots of hyphae (Bernard's peletons) in the cortical cells and also by single hyphal strands passing from cell to cell. Roots showing such fungi were again washed, this time with sterile water, and were then externally sterilized by immersion in a 1 per cent HgCl2 solution for five minutes. They were then rinsed in sterile water and placed in a sterile Petri dish where they were cut into one centimeter sections by means of a scalpel. All operations were performed under aseptic conditions. The root pieces were distributed on potato-dextrose agar in Petri dishesabout five to one dish. The dishes were then inverted and placed in an incubator at 25° C. Examinations were made frequently and all Rhizoctonias were transferred as soon as their purity could be ascertained. All other fungi which were obviously growing from the cortical tissues at the ends of the root piece were also transferred. It may be objected that this method might allow occasional root surface contaminants to appear on the isolation plates, but in practice such contaminants were very rare, as the mercury sterilizing agent was very efficient in killing the soil organisms adhering to the root. All other methods, such as the picking of individual fungus peletons from single cells by microtechnique, are open to the same objection of the occasional presence of external organisms and, in addition, are unsuited for rapid isolation from the large numbers of roots necessary in the present investigation.

All cultures were kept on potato-dextrose agar in tubes. They were transferred to thin layers of the same agar in Petri dishes for microscopic examination of the mode of spore formation and other developmental details. Cultures were also maintained in liquid media, using such solutions as Richard's and potato-dextrose. Microscope slide mounts were made by teasing out a bit of the spore-bearing hyphae from a plate culture, staining with either cotton blue or acid fuchsin, and mounting in lactophenol. The photomicrographs were made from such slides.

ORCHID RHIZOCTONIAS.—The fungi commonly thought of as orchid symbionts have been assigned to the genus Rhizoctonia DeC. Bernard placed them in this genus because of the marked resemblance of one of them (Rhizoctonia mucoroides Bern.) to Rhizoctonia violacea Tulasne. In general the orchid Rhizoctonias have the following characteristics: mycelium composed of white, orange, reddishbrown, dark brown, or black hyphae with vertical cross walls. Hyphal branches originate near the distal end of the long cells of the main hyphae; frequent anastomosing of the branches occurs. As the mycelium ages, short inflated moniliform filaments. rich in globular inclusions, arise in the same manner as the vegetative branches. They anastomose in some species, remain free in others. The filaments are soon cut up into varying numbers of more or less inflated cells, resembling spores. Additional "spore" cells are formed either by budding from the terminal cell or by basipetal abscission. The "spore" cells may be spread uniformly throughout the mycelium or be aggregated into larger or smaller groups of closely appressed and intertwined chains of cells, here termed sporodochia. The "spore" cells vary in different species from elongate cells of only slightly greater diameter than the vegetative hyphae to swollen, spherical cells many times larger than the normal hyphae.

Bernard (1904) was the first to isolate Rhizoctonias from orchids and the first to describe them as distinct species. He named three species—Rhizoctonia repens, Rhizoctonia lanuginosa, and Rhizoctonia mucoroides. Additional species have been described by Costantin and Dufour (1920), Wolff (1926), and Burgeff (1932, 1936). Table 1 lists the described species of Rhizoctonia, with their host plants and the dates of description.

Many of the fungi isolated from Wisconsin orchids may be definitely recognized as belonging to some of the above species. Others are intermediate in character, and still others are distinctly different. The value of creating new species to cover these distinct forms is perhaps questionable, since the perfect form of none of them has been described,

Table 1. The described orchid species of Rhizoctonia.

Fungus	Host	Date of description
R. repens Bernard	Laeliocattleya Canhamiana	1909
R. lanuginosa Bernard	Odontoglossum grande	1909
R. mucoroides Bernard	Phalaenopsis amabilis	1909
R. goodyera-repentis Costantin	Goodyera repens	1920
R. neottiae Wolff	Neottia nidus-avis	1926
R. aerea Burgeff	Taeniophyllum glandulifera	1932
R. arachnion Burgeff	Thrixspermum arachnites	1932
R. floccosa Burgeff	Myrmechis glabrae	1932
R. anomala Burgeff	Orchis maculata	1936
R. asclerotica Burgeff	Ophrys apifera	1936
R. gracilis Burgeff	Oncidium sphacelatum	1936
R. robusta Burgeff	Oncidium Ĉavendishianum	1936
R. sclerotica Burgeff	Ophrys muscifera	1936
R. Stahlii Burgeff	Platanthera chlorantha	1936
R. subtilis Burgeff	Lycaste Skinneri	1936

but if the species be considered form-species, such designation may be justified on the basis of greater convenience.

The following paragraphs list the *Rhizoctonia* species isolated in the present investigation, their host plants, and a brief description of each. All descriptions of growth characters and spore sizes are based on Petri dish and test tube cultures on potato-dextrose agar and Erlenmeyer flask cultures on a liquid potato-dextrose medium. The spore sizes are given in microns and represent the average range found in fully matured spores. The photomicrographs of all species are presented at the same magnification ( $\times 208$ ).

Rhizoctonia neottiae Wolff.—Sporodochia dark red-brown, large (1 mm. in diameter), open textured. Hyphae coarse, 9–10  $\mu$  in diameter, dark brown, producing irregular appressorium-like cells on short branches when growing next to glass. Spores elongate, 74–80  $\mu$  by 19–22  $\mu$ . Figure 142, page 141, Burgeff, 1936.

Isolated from: Aplectrum hyemale, low mixed hardwoods, Jefferson County, Wisconsin.

Rhizoctonia borealis n. sp.—Mycelium at first light tan, later dark brown. Sporodochia numerous, up to 3 mm. in diameter, distinct from the rapidly growing mycelium. Mat of aerial hyphae formed in liquid cultures. Spores clostridium-like,  $37-42~\mu$  by  $24-28~\mu$ . Figure 1. Very similar to R. mucoroides Bernard except for the much greater size. The hyphal tips exhibit an unusually regular dichotomous branching prior to spore formation.

Isolated from: Goodyera repens var. ophioides, balsam-spruce swamp, Vilas County, Wisconsin; Spiranthes gracilis, sandy opening in coniferous forest, Vilas County, Wisconsin.

Rhizoctonia gracilis Burgeff.—Mycelium white. Sporodochia yellow, waxy, coalescing. Spores very elongate, only slightly greater in diameter than the vegetative hyphae,  $42-45~\mu$  by  $10-12~\mu$ . Figure 132, page 136, Burgeff, 1936.

Isolated from: *Habenaria lacera*, tamarack-sphagnum bog, Ozaukee County, Wisconsin.

Rhizoctonia robusta Burgeff.—Mycelium white. Sporodochia small, orange, waxy. Spores keg- or barrel-shaped,  $32-34~\mu$  by  $25-28~\mu$ . Figure 2.

Isolated from: *Habenaria leucophaea*, wet *Rynchospora* swale in tamarack bog, Ozaukee County, Wisconsin.

Rhizoctonia lanuginosa Bernard.—Mycelium white. Sporodochia yellowish, waxy, opalescent. Spores elongate, widest beyond the middle,  $20-23 \mu$  by  $10-16 \mu$ . Figure 3.

Isolated from: Goodyera tesselata, virgin hemlock forest, Vilas County, Wisconsin; Calopogon pulchellus, low prairie, Waukesha County, Wisconsin.

Rhizoctonia Stahlii Burgeff.—Abundant white aerial hyphae. Sporodochia yellow, large, opentextured, not waxy, mostly 1 mm. or less in diameter. Spores elongate, 26–34 μ by 14–18 μ. Figure 4.

Isolated from: Habenaria leucophaea, low prairie, Jefferson County, Wisconsin; Spiranthes cernua, moist meadow, Waukesha County, Wisconsin; Habenaria psycodes, moist meadow, Iowa County, Wisconsin.

Rhizoctonia sclerotica Burgeff.—Abundant white aerial hyphae. Sporodochia orange, compact, not waxy, at length very large, 5 mm. or more in diameter. Spores rare, except in sporodochia, 20–22  $\mu$  by 12–14  $\mu$ . Figure 5.

Isolated from: Cypripedium reginae, moist meadow, Columbia County, Wisconsin; Habenaria leucophaea, wet Rynchospora swale in tamarack bog, Ozaukee County, Wisconsin; Notylia trisepala, Oaxaca, Mexico; Spiranthes cernua, low prairie, Jefferson County, Wisconsin.

Rhizoctonia subtilis Burgeff.—Mycelium at first light tan, later becoming uniform light brown, recumbent, smooth, glistening. Sporodochia small, confluent over surface of mycelium. Spores in irregular, zig-zag, or unevenly angular chains, 8-11  $\mu$  by 5-8  $\mu$ . Figure 6.

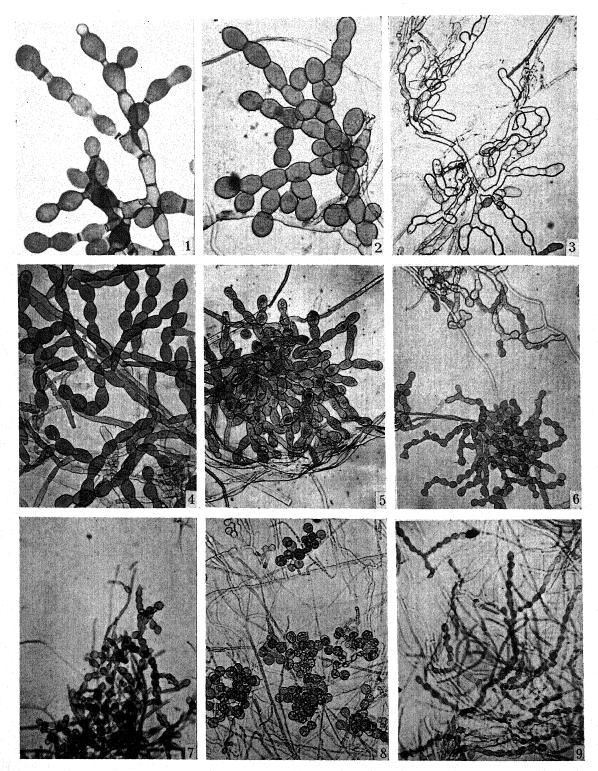

Fig. 1-9. Rhizoctonia species.—Fig. 1. R. borealis.—Fig. 2. R. robusta.—Fig. 3. R. lanuginosa.—Fig. 4. R. Stahlii.—Fig. 5. R. sclerotica.—Fig. 6. R. subtilis.—Fig. 7. R. subtilis var. nigra.—Fig. 8. R. repens.—Fig. 9. R. monilioides. All ×208.

Isolated from: Cypripedium candidum, moist meadow, Columbia County, Wisconsin; Cypripedium parviflorum, moist meadow, Columbia County, Wisconsin; Habenaria leucophaea, Rynchospora swale in tamarack bog, Ozaukee County, Wisconsin; Trichopila tortilis, Volcano San Martin, Vera Cruz, Mexico.

Rhizoctonia subtilis var. nigra n. var.—Sporodochia rare or absent. Mycelium recumbent, smooth, glistening, black, producing a black discoloration on agar. Spores infrequent, irregular and variable in shape, often constricted in the middle,  $10-13~\mu$  by  $7-9~\mu$ . Hyphae slender,  $2~\mu$  in diameter. Distinguished from the preceding by the color and by the larger size of the spores. Figure 7.

Isolated from: Spiranthes cernua, low prairie,

Jefferson County, Wisconsin.

Rhizoctonia repens Bernard.—Mycelium white, recumbent, creeping, no aerial hyphae. Sporodochia small, white, confluent in a continuous layer over the surface of agar media. Spores nearly spherical, in staphylococcoid cluster of short branched chains,  $13-19~\mu$  by  $10-14~\mu$ . Figure 8. Mycelium entirely submerged in liquid cultures.

Isolated from: Brassia giveoudiana, San Isidro, Costa Rica; Calopogon pulchellus, moist prairie, Waukesha County, Wisconsin; Goodyera pubescens, pine covered talus slope, Sauk County, Wisconsin; Goodyera repens var. ophioides, hemlock woods,

Sheboygan County, Wisconsin; Habenaria psycodes, moist quartzite ravine, Sauk County, Wisconsin; Liparis Loeselii, sphagnum bog, Ozaukee County, Wisconsin; Pogonia ophioglossoides, open sphagnum bog, Ozaukee County, Wisconsin; Spiranthes cernua, habitat unknown, Hanover, New Hampshire.

Rhizoctonia monilioides n. sp.—Cottony aerial hyphae present on agar cultures. Sporodochia absent. Spores in long (10–18 spores), branched, monilioid chains, 10–14  $\mu$  by 7–10  $\mu$ . Growth in liquid culture similar to that of R. repens. Separated from that species because of the very long spore chains, the slightly smaller spores, and the

absence of sporodochia. Figure 9.

Isolated from: Habenaria dilatata, wet Rynchospora swale in tamarack bog, Ozaukee County, Wisconsin; Habenaria hyperborea, shaded sphagnum bank, Ozaukee County, Wisconsin; Liparis liliifolia, rocky, dry, pine woods, Sauk County, Wisconsin; Pogonia ophioglossoides, wet Rynchospora swale in tamarack bog, Ozaukee County, Wisconsin; Sobralia pleiantha, San Isidro, Costa Rica; Spiranthes Romanzoffiana, tamarack-sphagnum bog, Vilas County, Wisconsin.

It will be noted from the isolation data of the preceding fungi that most of them were found in more than one orchid species. More important, however, is the observation that the same orchid spe-

cies may harbor more than one species of Rhizoctonia. In one instance R. robusta and R. subtilis, two very different species, were isolated from the same root piece of Habenaria leucophaea (Curtis, 1937). Table 2 lists the species of orchids and the

species of fungi isolated from them.

Both Habenaria leucophaea and Spiranthes cernua harbored four distinct fungus species, and it seems quite probable that the number of species found in the other orchids was limited only by the lack of a sufficient number of isolations. This is particularly true in the Goodyeras, where only a few plants were available. In Cypripedium, a great many isolations were attempted, not only from C. candidum, C. parviflorum, and C. reginae, but also from C. acaule, C. arietinum, and C. pubescens. Only three Rhizoctonias were obtained in more than twenty-five trials. In most of the attempts, the excessive amount of raphides and other crystals in the root cells apparently prevented the growth of the fungi present or had caused their death while still within the living root.

From table 2 it will be seen that there is no apparent specificity about the infection of orchids by Rhizoctonia species. Any one orchid may be infected by several species of fungi, and the same fungus may infect widely separated species of orchid. Even when grouped into the larger unit of the tribe, the orchids show no tendency to be infected by any specific fungus or group of fungi. The only statement that can be made is that orchids on the whole are subject to attack by various species of fungi, with the genus Rhizoctonia furnishing the largest number and the most common parasites of

the group.

Previous work (Curtis, 1937) has indicated that there might be a correlation between fungus species and the habitat of the host orchid. Additional proof of this contention was found in the present investigation. Thus, Rhizoctonia sclerotica was obtained from orchids growing in a low prairie, in a moist open meadow, and in a Rynchospora swale in a tamarack bog. All these locations were similar in that they were fairly moist, were exposed to the full sun, and had a soil reaction between pH 7.2 and 7.6. Again, R. Stahlii was isolated from three species of orchids growing in essentially the same conditions as the hosts of R. sclerotica—an open meadow, and two low prairies, with the same conditions of moisture, light, and soil reaction. Burgeff (1936) states that R. Stahlii is found in orchids growing in damp situations-"Meist Pilze von Orchideen feuchterer Standorte." He isolated it from Platanthera, Ophrys, and Coeloglossum, all typical orchids of the alkaline European chalk meadows.

Another example is Rhizoctonia borealis, found only in the acid soil areas of the Canadian Zone coniferous forest. R. subtilis and its variety nigra occurred only in moist, open, alkaline habitats—a moist meadow, a low prairie, and an alkaline swale in a tamarack swamp.

On the other hand, Rhizoctonia lanuginosa, R. repens, and R. monilioides show no such limitations as to ecological requirements. The former occurred in an acid forest and an alkaline meadow in Wisconsin and has been isolated from several epiphytes of the American tropics. R. repens has been isolated from orchids growing in a great range of habitats in Wisconsin. Other investigators have isolated it from a number of tropical orchids of widely different ecological distributions. However, since most of these isolations were made from greenhouse or conservatory grown specimens, nothing definite can be said about the natural range of R. repens. In this connection it is of interest to point out that of the eleven isolations of this species made by Bernard, eight came from one greenhouse, two from another, and one from a third. He also found R. mucoroides in Vanda and Phalaenopsis from one greenhouse and found it in the fern Ophioglossum in the same

With most species the correlation between type of habitat and the species of fungus found in orchids growing in that habitat seems quite distinct. For example, in Wisconsin, any moist, open, alkaline meadow or swale would be expected to harbor Rhizoctonia sclerotica, R. Stahlii, and R. subtilis. Any orchid growing in such a habitat might be infected by any one or more of these forms, with no specific relationship between the species of orchid and the species of fungus. All three, for instance, have been found in Habenaria leucophaea.

All the evidence from these isolations points to the conclusion that the various Rhizoctonia species are soil saprophytes of either widespread or more restricted distribution, and that they may become facultative parasites, attacking the roots of any orchids in the immediate vicinity. These isolation results do not, by themselves, show that there is no symbiotic relation between orchid and fungus. It might be argued that, although more than one fungus can enter the roots of an orchid, only one is of benefit in seed germination. It will be remembered that the ability to induce seed germination is the main proof of a true mutual symbiosis offered by

the proponents of the symbiotic theory.

In order to test this possibility, a series of experiments was conducted in which all the fungi isolated from an orchid were planted in symbiotic cultures with the seeds of that orchid. Fungi isolated from other orchids were also planted with the same seeds. Burgeff's medium Sb (1936) at pH 5.2—the test solution recommended for determining the germinating power of fungi-was used as a substrate throughout. The controls were planted on the same medium except that the carbohydrate source was glucose, rather than starch, as orchid seeds cannot be expected to grow in non-symbiotic culture when provided with an insoluble carbohydrate. The results are shown in table 3. Although rather limited in number, these results tend to show that the fungi isolated from an orchid are not necessarily capable of germinating its seeds. In the

Table 3. Results of symbiotic germination tests, 0 indicates no germination. × indicates good germination, and the underline indicates those trials in which the fungus used was isolated from the species bearing the seeds.

case of Habenaria leucophaea and Liparis Loeselii, where no germination occurred in any instance, the results might be interpreted as being due to poor seeds, but since the seeds were freshly collected and apparently viable, the results are probably valid.

Numerous other examples of a similar nature are to be found in the literature. Bernard (1904) was unable to germinate the seeds of Spiranthes autumnalis with Rhizoctonia repens isolated from that orchid. He also noted that fungi isolated from the same Cattleya plant at different times of the year varied greatly in their ability to induce germination of Cattleya seeds. Burgeff (1909) was unable to germinate the seeds of seventeen European terrestrial orchids (including three genera and two species of North American distribution) with their own fungi or with fungi of other temperate orchids.

In other experiments with terrestrial orchids of Java, Burgeff (1936) found that the seeds of eleven species of eight genera failed to germinate when planted with fungi isolated from them or isolated from other species of the same genera. He also found that Rhizoctonia mucoroides isolated from Phalaenopsis equestris would bring about the germination of seeds of Vanda and Euanthe, but not those of Phalaenopsis schilleriana, P. Aphrodite, nor P. stuartiana.

Ramsbottom (1927) also noted instances of the occurrence of fungi in orchid roots that would not induce germination of that orchid's seeds. He says, "Several isolations of the Cattleya fungus were made. These fungi varied to a great extent, and with the first two or three sets of them no great success in germination was attained. . . After a short time a strain was isolated which gave a totally different picture for Cattleya. Here germination occurred in a most astonishing way . . . one could almost guarantee over ninety per cent germination."

According to Ames (1938), J. N. Porter found that the seeds of Zeuxine strateumatica would not

germinate when planted with a species of *Rhizoctonia* isolated from the roots of that orchid. This is especially interesting, since *Zeuxine* is an introduced species that has been spreading throughout the State of Florida in recent years and apparently germinates readily under field conditions.

A similar line of evidence is presented by the numerous instances of orchid seeds induced to germinate by fungi other than those isolated from the roots of the seed-bearing species. Thus Cypripedium reginae would not germinate with Rhizoctonia sclerotica from that orchid, but would germinate with R. repens from Pogonia ophioglossoides and with R. monilioides from Liparis liliifolia. Again, Bernard (1909) reported germination of Brassolaelia with R. mucoroides from Phalaenopsis and of Vanda with R. lanuginosa from Odontoglossum. He also reported that R. mucoroides induced better germination of Cymbidium seeds than did R. repens isolated from Cymbidium. Burgeff (1936) pointed out that R. repens isolated from the North American terrestrial orchid Habenaria psycodes was able to induce germination of seeds of Angraecum from Madagascar, of a large number of tropical epiphytes from Central and South America, and of both epiphytic and terrestrial orchids from the Indomalayan mountains.

Discussion.—A review of these results indicates that the roots of orchids are easily infected by various saprophytic fungi, among which various species of Rhizoctonia are especially common. The Rhizoctonia species vary widely in their ecological requirements and probably also in their geographical distribution. Those growing in any particular location are apt to infect any orchids growing in that same location. If the orchids are capable of growing in several types of habitat, they are open to a greater variety of infection than if they are restricted to a single habitat. In any case they may be infected by several species of Rhizoctonia, since more than one fungus species is found in most loca-

tions and in addition at least one species (R. repens) is apparently almost universal in distribution.

When seeds of any orchid are planted on an essentially unfavorable medium, such as one containing starch or other insoluble carbohydrate supply, germination may be induced by an appropriate fungus inoculated on to the culture. This fungus may or may not be a member of the genus Rhizoctonia. If not, it may be a basidiomycete (Pleurotus, Corticium, Hypholoma, Marasmius), an ascomycete (Ceratostomella, Penicillium, Chaetomium), or a phycomycete (Phytophthora, Choanophora). If a Rhizoctonia, it need not be one which grows in the roots of that orchid or in closely related orchids. Indeed, the fungi from many orchids will not induce the germination of the seeds of those orchids and may be definitely injurious to them.

When the freshly collected seeds of a great many orchids are planted non-symbiotically on a favorable medium, such as one containing a mineral nutrient solution of low osmotic concentration, a soluble carbohydrate supply, and nitrogen in the form of some complex proteinaceous compound, germination and subsequent development proceed in a normal fashion. In the case of old seeds of certain orchids (i.e., Cymbidiinae and Sarcanthinae) the addition of certain growth substances may be necessary to bring about successful germination.

The evidence offered here showing that there is no specific relation between fungus species and orchid host, and the demonstration by other investigators that orchid seeds may germinate without the aid of any fungus or with fungi unrelated to *Rhizoctonia*, both point to the conclusion that the mycorrhizal association is devoid of mutualistic significance.

#### SUMMARY

The arguments in favor of the existence of a mutually beneficial symbiosis between orchids and fungi are considered to be successfully refuted by the work of Knudson and others, except for the hypothesis of specificity of the orchid-fungus relationship. To test this theory, isolations of mycorrhizal fungi were made from 23 species of orchids from various habitats in the United States and Mexico. Ten species of Rhizoctonia were obtained. including two new species, Rhizoctonia borealis, n. sp., and R. monilioides, n. sp. No evidence of specificity could be found, as one orchid species could harbor as many as four distinct fungus species, and one fungus species could attack at least seven different orchids of four distinct tribes. There appeared to be a correlation of fungus species with ecological habitat, rather than with orchid species. A few fungi were found which occurred in a wide variety of habitats.

Symbiotic germination tests were made, using all the fungi isolated from a given orchid in combination with the seeds of that orchid. The results supported the above contention of non-specificity, since the fungi isolated from an orchid were in most cases unable to induce germination of that orchid's seeds. In view of both Knudson's demonstration that the fungus is unnecessary for germination and the evidence offered here that the orchid-fungus relation is non-specific, it is concluded that the symbiotic relationship is one of parasite and host, with the orchid deriving no benefits from the fungus in its roots.

# THE ABSORPTION OF PHOSPHATE AND NITRATE BY ILLUMINATED CULTURES OF NITZSCHIA CLOSTERIUM $^{\rm 1}$

## Bostwick H. Ketchum

The researches of Brandt (1899, 1902) first called attention to the importance of phosphate and nitrate as factors limiting phytoplankton growth in the sea. Numerous investigations have since been made using accurate analytical methods, and the results show that during the growth of the phytoplankton, phosphate and nitrate may be removed completely from the water (Atkins, 1923, 1926a, 1926b; Cooper, 1933; Harvey, 1926, 1928; Harvey et al., 1935; Kreps and Verjbinskaya, 1932; Marshall and Orr, 1928). Some results indicate that the growth of phytoplankton ceases when these ions have completely disappeared from the water (Marshall and Orr, 1928).

The conclusions reached by study of the variables in the sea have been corroborated by laboratory experiments. Schreiber (1928) determined the total number of diatoms which could be grown in water collected at various times of the year and found a good correlation between the concentration of phosphate and the crop. Braarud and Foyn (1931) showed that nitrate can also limit diatom growth.

Although the concentrations of phosphate and nitrate in sea water vary between wide limits, Redfield (1934) showed that they vary in a related fashion. The ratio of concentrations in the waters of the West Atlantic, South Atlantic, Pacific, and Indian Oceans and Barents Sea is about one atom of phosphorus to twenty atoms of nitrate nitrogen. Redfield also shows that the proportions of carbon, nitrogen, and phosphorus in typical hawls of various plankton are nearly the same as the proportions found in the sea water. He pointed out that these relations do not obtain in water bodies of limited extent, such as the English Channel, the Gulf of Maine, etc., where local conditions may alter the picture. Cooper (1937) discusses the departure from the usual ratio in the English Channel and in the Mediterranean Sea but offers no explanation for these anomalies.

Redfield (1934) states: "Whatever its explanation, the correspondence between the quantities of biologically available nitrogen and phosphorus in the sea and the proportions in which they are utilized by the plankton is a phenomenon of the greatest interest."

<sup>1</sup> Received for publication April 4, 1939.

Contribution No. 216 of the Woods Hole Oceanographic

The author expresses his sincere thanks to Professor Alfred C. Redfield, who suggested this problem, for his generous assistance and advice.

The absorption of phosphate and nitrate by pure cultures of a marine diatom has been studied to determine what effect its growth might have upon the ratio of these ions in the water. This paper presents data relating the absorption of phosphate and nitrate by cells grown under continuous illumination to the concentration of these ions in the medium. In those ranges of concentration normally found in the sea the rate of absorption per cell is dependent on the concentrations of the nutrient in the water. The rate of phosphate absorption is dependent on both the nitrate and the phosphate concentration, while the rate of nitrate absorption is dependent on the concentration of nitrate in the medium and independent of the phosphate concentration.

As a consequence of this relationship the ratio in which phosphate and nitrate are absorbed is dependent on the concentration of phosphate in the medium and independent of the nitrate concentration over large ranges. The growth of the cells changes the proportions in which phosphate and nitrate are present in the medium. Under certain conditions the metabolism of the cells brings the ratio of phosphorus to nitrogen closer to the usual value found in the sea; under other conditions it increases an original departure from this ratio.

Material and methods.—The marine diatom, Nitzschia Closterium, which was used in this work was grown in the medium suggested by Ketchum and Redfield (1938). Stock cultures in 500 cc. Erlenmeyer flasks were prepared regularly and were grown in the light of a north window. These cultures were seeded with a concentration of 50,000 cells per cc. and contained, at the end of five or six days, about two million cells per cc. At this time they were used as seed for the new stock and for the experimental work. Tests for bacteria were made regularly by plating on the medium described by Reuszer (1933), as well as by the methods suggested by Barker (1935a). All the experiments described were performed on bacteria-free cultures.

The phosphate in the medium was measured by the Deniges-Atkins ammonium molybdate method, using stannous chloride as the reducing agent (Atkins, 1923). Since the cells present in the medium give the solution a greenish color which will not match with the standards, the cultures were filtered through a barium sulphate precipitate on a cintered glass filter, as suggested by Redfield, Smith, and Ketchum (1937). Salt effect and blank corrections were always made (cf. Redfield et al.).

The nitrate nitrogen in the medium was measured by the reduced strychnine method described by Harvey (1926) for use in sea water. The modifications introduced by Rakestraw, as discussed by Wattenburg (1937), were used throughout. The color was allowed to develop for eight hours and was compared in a bicolorimeter with standards consisting of methyl orange in 0.001 normal HCl. Concentrations ranging from 5 to 100 gamma (grams ×10<sup>-6</sup>) of nitrogen per liter can be measured directly. Higher concentrations must be measured by dilution with "nitrate free" sea water. Corrections were made for the amount of nitrate added in the diluting water. The reagent measures both nitrate and nitrite nitrogen. The latter is always present in relatively low concentrations, and nitrate was used for enrichment of the culture medium. The measurements were recorded, therefore, as nitrate. All figures given in the paper are the average of two or more check analyses.

The experimental cultures were grown in a specially constructed air chamber. An electric refrigerating unit is set into one-half of the top of an insulated box. The other half is occupied by a window consisting of two sheets of glass, separated by one and one-half inches of insulating air space. The inner sheet is finely ground in order to diffuse the light. The light source consists of four 100-watt lamps mounted on the corners of a twenty-inch square of plywood, the center of which is occupied by a 75-watt bulb. The bulbs are an inch above the outer glass plate. The cultures are supported by a shelf within the chamber ten inches below the glass window. This lighting arrangement gives uniform illumination on the shelf which is more than adequate to produce maximal growth in the cultures when the cell concentration is 50,000 cells per cc. The temperature is controlled by a mercury thermoregulator, the air being circulated by an electric fan.

EXPERIMENTAL RESULTS.—The absorption of nitrate.—In order to determine the effect of the concentration of phosphate in the medium on the rate of absorption of nitrate, experiments were performed in the following way: cells from a stock culture which had been grown in the light of a north window for six days were placed in fresh sea water,

and the cell concentration was adjusted to 50,000 cells per cc. The suspension was enriched with nitrate and then divided in flasks. Different amounts of phosphate were added to each flask. The cultures were placed in the dark for twelve hours and were then placed in the light at a temperature of 16°C. The rate of absorption was determined by the difference between the nitrate present when the cultures were placed in the light and the final concentration of nitrate in the medium. Any differences in the rate of absorption of nitrate under these conditions may be attributed to the different phosphate concentrations, since all other variables are controlled.

The results of three experiments performed in this way at different nitrate concentrations are presented in table 1. In each experiment the phosphate concentration varies between less than ten and about one hundred gamma per liter. The data show that this tenfold increase in the concentration of phosphate has no influence on the rate of absorption of nitrate from the medium.

Since these experiments were performed at three different nitrate concentrations they show the effect of the concentration of nitrate on the rate of its absorption. The cells suspended in the medium containing about 240 gamma of nitrate nitrogen per liter absorbed two and one-half times as much nitrogen as those in the medium containing only fifty gamma per liter.

In order to study in more detail the relation between the concentration of nitrate in the medium and the rate of absorption of nitrate, experiments were performed in which the nitrate concentration was different in the various cultures. Although the phosphate concentration in these cultures was not equal, the data presented in table 1 show that this does not affect the rate of nitrate absorption. The results are summarized in table 2, where they are arranged according to the original concentration of nitrate in the medium. The rate of absorption increases steadily with the increase in the concentration of nitrate in the medium. In figure 1 the relation between the average concentration of nitrate in the medium and the rate of absorption of nitrate by the cells is shown. The data from tables 1 and 2

are included in this figure. Although the experimental variation is large at the high concentrations of nitrate, since these must be measured by dilution, the increasing rate of absorption with increasing concentration is plainly demonstrated. Above a concentration of about 200 gamma nitrate nitrogen per liter the rate of absorption of nitrate appears to approach a limiting value.

These experiments show that although the rate of absorption of nitrate is independent of the concentration of phosphate, it is directly related to the concentration of nitrate in the medium.

The absorption of phosphate.—In the utilization of phosphate by diatoms two types of absorption can be distinguished. Absorption from the medium always occurs when the cells are grown in the light, provided phosphate is available. Phosphate is also absorbed in the dark by cells which are deficient in phosphorus, as described in another paper (Ketchum, 1939). Since this effect is so pronounced, it is necessary to be certain that it is not confusing the results obtained in the study of the absorption

by illuminated cultures. It was found that stock cultures should be no more than five or six days old when used. Cells from such a culture are resuspended in fresh sea water and placed in the dark for a period of twelve or more hours. By this time the "phosphate debt" is satisfied. The cultures are then placed in the light, and the absorption of phosphate from the medium may be measured.

Experiments were performed on cells prepared in this way to determine the influence of the phosphate concentration in the medium on the rate of absorption of phosphate. The cultures were divided in flasks which were placed in the light at 16°C. after the addition of a different amount of phosphate to each flask. The phosphate concentration was measured when they were placed in the light, and the rate of absorption was determined by the difference between this and the final concentration of phosphate in each case.

The results of three experiments performed in this way at three different nitrate concentrations are presented in table 3 and figure 2. In each ex-

periment the rate of absorption of phosphate increases with an increase in the phosphate concentration in the medium. The rate of absorption of phosphate also depends on the concentration of nitrate in the medium, as comparison of the results obtained at the three different nitrate concentrations shows.

The experiment in which the cultures contained no nitrate is particularly interesting. Since nitratefree sea water is difficult to obtain, a culture was allowed to grow until no nitrate could be detected in the medium by the reduced strychnine method. It was then divided in four flasks and a different amount of phosphate added to each flask. After six hours in the light a definite absorption of phosphate was measured, showing a dependence of the rate of absorption on the phosphate concentration which is similar to that demonstrated by the other two experiments. From this experiment it is clear that the cells are able to absorb phosphate from the medium, even when no measurable nitrate is present. Comparison with the other two experiments, however, shows that the presence of nitrate materially increases the rate of absorption of phosphate.

Experiments were also performed to study the effect of the concentration of nitrate on the rate of absorption of phosphate from the medium. In each of these experiments the original concentration of phosphate was equal, whereas the concentration of nitrate was different in the various flasks. The amount of phosphate absorbed by the cells was determined by the difference between the initial concentration of phosphate and the concentration after a period of illumination at 16°C. The results of five experiments performed in this way are presented in table 4 and figure 3, where the values plotted for the zero concentration of nitrate are taken from the experiment reported in figure 2. Again a family of curves is obtained which shows the dependence of the rate of absorption of phosphate on the concentrations of both phosphate and nitrate. Each curve of the family was obtained for a different concentration of phosphate, which is given by the figure at the end of the curve. All the curves show a relation between the rate of absorption of phosphate and the nitrate concentration. Intercomparison of the curves shows that, for a given concentration of nitrate, the rate of absorption of phosphate increases with increasing concentrations of phosphate.

The rate of growth under the experimental conditions used.—It was possible that the various experimental conditions used might influence the rate

the rate of absorption of phosphate by illuminated cultures of Nitzschia Closterium at 16°C. and the concentration of nitrate in the medium at five different phosphate concentrations. The figure at the end of each curve shows the phosphate concentration at which that experiment was performed, units gamma per liter. Ordinate, phosphate absorbed per cell per hour, units gamma  $PO_4 \times 10^8$ . Abscissa, concentration of nitrate in the medium, units gamma N per liter.

of growth of the cells and thus indirectly control the rate of absorption of phosphate and nitrate. Experiments were therefore performed to discover what effect the concentrations of nitrate and phosphate in the medium have upon the rate of growth. These experiments were done in the same way as those reported above, except that they were grown in the light of a north window instead of in the artificially illuminated air bath. Longer periods of time were used in these experiments in order to obtain significant differences in the cell counts. A di-

rect measure of the rate of growth is given by the division rate per cell (k), which is defined by the equation  $k=1/t\left[\ln C_{\rm t}/C_{\rm o}\right]$  in which  $C_{\rm t}$  and  $C_{\rm o}$  are the cell counts at the end and beginning of time t.

The results of the experiments are summarized in table 5. In the first experiment the effect of the nitrate concentration on the rate of growth was studied. All these cultures were started with an equal phosphate concentration, and the nitrate concentration varied from 47 to 525 gamma per liter.

All the experiments on the absorption of nitrate from the medium were performed within this range of concentrations. The rate of growth in all these flasks was nearly constant in spite of this tenfold increase in the concentration of nitrate.

The second, third, and fourth experiments reported in table 5 relate the rate of growth with the concentration of phosphate in the medium. They show that between 50 and 150 gamma of phosphate per liter the rate of growth is independent of the phosphate concentration. Below a concentration of 50 gamma of phosphate per liter, however, the rate of growth is limited by the concentration of phosphate in the medium.

Since the rate of growth is constant at different concentrations of phosphate and nitrate, the differences in the rate at which these ions are absorbed is not due to different growth rates. Concentrations of phosphate below 50 gamma per liter, however, may limit the rate of absorption of phosphate indirectly by affecting the rate of growth. It is interesting to note that such low concentrations of phosphate have no influence on the rate of absorption of nitrate (see table 1). It appears, therefore, that in these experiments the effect of the rate of growth is negligible in comparison with the direct effect of the concentration of the nutrients on the rate of absorption.

Since the rate of absorption of phosphate and nitrate was measured on illuminated cultures, cell division must have taken place. The growth rates recorded in table 5 indicate that the cells would almost double in number in the eight to ten hours of continuous illumination allowed for these experiments. The rates of absorption have been expressed in terms of the initial number of cells in the culture. No correction for the amount of growth has been made. Expressed in this way the results are comparable for all experiments except those containing less than 50 gamma of phosphate per liter, where lower rates of growth are observed.

Ratio of absorption.—From the data concerning the rate of absorption of phosphate and nitrate from media of various compositions it is possible to predict the ratio in which these ions will be absorbed from media in which they occur in any proportion. The ratio in which phosphate and nitrate are absorbed at seven phosphate and six nitrate concentrations have been calculated, using the rates of absorption obtained from figures 1, 2, and 3. These are presented in table 6, where they are grouped according to the phosphate concentration, each group containing the data for six nitrate concentrations. The ratio of absorption,  $\Delta P : \Delta N$ , is constant in each group, even though the nitrate concentration varies between 10 and 300. It will be remembered that the rate of absorption of both nitrate and phosphate are dependent upon the nitrate concentration. The effect of the nitrate upon the absorption of these two ions must be similar or the constant ratio would not be obtained. This similarity is not found at low nitrate concentrations, since these limit the rate of absorption of nitrate to a greater extent than the rate of absorption of phosphate. An increase in the value for the ratio of absorption is observed for these low nitrate concen-

Intercomparison of the groups shows that the value for the ratio increases with increasing concentrations of phosphate.

In the fifth column of the table the ratio in which phosphate and nitrate are present in the medium is shown. For each phosphate concentration these vary thirtyfold, since the nitrate concentration varies between 10 and 300. Comparison of these figures with the ratio of absorption shows that the latter is completely independent of the proportions of nitrate to phosphate in the medium.

Under normal conditions of growth both phosphate and nitrate are being continuously removed from the medium. Since the concentration of phosphate in the medium determines the ratio in which these ions are absorbed, this ratio must constantly change while the cells are growing. In figure 4 the changes in the medium during constant growth of the cells are presented. The light lines show the changes in the medium predicted from the data in table 6. Simultaneous measurements of the phosphate and nitrate remaining in the medium after various periods of illumination were made on a num-

ber of cultures. These data are included in figure 4, where the points represent the composition of the medium at various times. The heavy lines connecting these points show how the growth of the

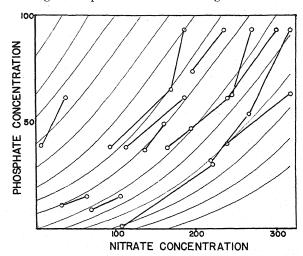

Fig. 4. The simultaneous removal of phosphate and nitrate from sea water of various compositions. The light lines show the changes predicted in table 6 from the data on the rate of absorption. The points, connected with heavy lines, show the changes observed when simultaneous measurements of phosphate and nitrate concentrations are made on actively growing cultures. Ordinate concentration of nitrate in the medium, units gamma N per liter. Abscissa concentration of phosphate in the medium, units gamma  $PO_4$  per liter.

cells changes the composition of the medium. The changes observed in these cultures agree closely with the predicted changes in the medium.

The usual ratio of phosphate phosphorus to nitrate nitrogen in the sea would be represented in figure 4 by a line drawn from the origin through the medium containing 298 gamma of nitrate nitrogen and 100 gamma of phosphate (PO<sub>4</sub>). It is apparent that this line does not coincide with the way in which phosphate and nitrate are absorbed by the cells. If the ratio P:N in the medium is high, the metabolism of the cells brings the ratio closer to the usual one; if the ratio is low, the metabolism of the cells increases the original departure from the usual ratio.

Discussion.—Schreiber (1928) and Braarud and Foyn (1931) found that the growth of unicellular algae is limited by low concentrations of phosphate and nitrate, respectively. In their experiments the concentrations of the nutrients studied was low, and they were undoubtedly exhausted before the end of the experiments. Such experiments certainly show that a deficiency of an essential element reduces the total crop which can be produced in a given medium, but no conclusions can be drawn concerning the rate of growth at a given concentration. Barker (1935b) showed that the rate of growth of marine dinoflagellates is inde-

pendent of the concentration of nitrate in the medium. The concentrations used in his work were sufficiently high so that they were not exhausted. The data presented in this paper confirm Barker's conclusions, since the rate of growth of Nitzschia Closterium is independent of the concentration of nitrate and phosphate over the concentration range of natural sea water.

It has been commonly assumed that low concentrations of a nutrient in natural waters limit the rate of growth and the rate of absorption of the nutrient simultaneously. The data presented in this paper show that this is not always true. The rate of absorption of both phosphate and nitrate varies in media containing different concentrations of these ions, even though the rate of growth is independent of their concentrations.

The data concerning the proportions in which nitrate and phosphate are absorbed indicate that at least two synthetic processes involving phosphorus are taking place and that these reactions are rigorously controlled by the concentration of both phosphate and nitrate in the medium. One of these reactions apparently involves both nitrogen and phosphorus metabolism and is controlled by the concentration of nitrate in the medium. It will be remembered that regardless of the concentration of nitrate in the medium the proportion in which phosphate and nitrate are absorbed is constant for a given phosphate concentration. Since the different nitrate concentrations influence the rate of absorption of both phosphate and nitrate, these rates must increase in direct proportion, as though a compound containing both nitrogen and phosphorus were being synthesized.

Phosphorus must also be utilized in reactions which do not involve nitrogen. The rate at which these reactions proceed must be dependent on the concentration of phosphate in the medium, since increased concentrations of phosphate increase the

rate of absorption of phosphate with no influence on the rate of absorption of nitrate.

The various reactions involving phosphorus can be most readily studied in unicellular forms, since the rates at which they proceed can be so easily controlled. This study is being extended to the formation of various organic compounds of phosphorus under the conditions discussed in this paper.

#### SUMMARY

The rate of absorption of nitrate by the marine diatom, Nitzschia Closterium, is independent of the concentration of phosphate in the medium, but it increases as the concentration of nitrate in the medium increases.

The rate of absorption of phosphate is directly dependent on the concentration of both phosphate and nitrate in the medium.

The rate of growth is independent of the concentrations of phosphate and nitrate in the medium except for phosphate concentrations of less than 50 gamma per liter, when it decreases.

The ratio in which phosphate and nitrate are absorbed is constant for each concentration of phosphate in the medium, regardless of the concentration of nitrate, except that at very low concentrations of nitrate the ratio of absorption increases.

The ratio of absorption  $\Delta P : \Delta \tilde{N}$  increases as the concentration of phosphate in the medium increases.

The normal course of absorption in cultures does not directly correspond to the usual ratio found in sea water. If the cells are in a medium in which the ratio of concentrations is somewhat higher than usual, the absorption by the cells tends to reduce the ratio toward the usual value. If the ratio of concentrations is lower than usual, the metabolism tends to increase the discrepancy.

## STUDIES OF SOUTH AMERICAN PLANTS. VIII. NEW AND NOTEWORTHY SPECIES OF LECYTHIDACEAE <sup>1</sup>

A. C. Smith

No comprehensive monograph of the Lecythidaceae has been published other than that of Miers, since which an abundance of herbarium material has been collected in tropical America. Many species of the family have been described since 1874, but no keys to species in the large genera, such as Eschweilera, have been published, with the exception of those in Eyma's excellent treatment3 of the Surinam species. In Amazonian Brazil and the Guianas alone, more than 80 names have been referred to Eschweilera. Although some of these will doubtless fall into synonymy, there certainly remain many species yet to be collected, and one may anticipate that the genus will eventually include at least 150 species in its entire range. As most members of the family are large trees with very hard wood, they have been neglected by most collectors until recently.

The following notes are based upon material in the herbarium of the New York Botanical Garden, in which types of the new species are deposited.

GUSTAVIA PLEUROCARPA Pittier. Colombia: Bolivar: Puerto Canoa to Salvajin, on Rio Esmeralda, Pennell 4548. Santander: Vicinity of Puerto Wilches, on Rio Magdalena, Killip & Smith 14904. The species has previously been reported only from the vicinity of the Panama Canal Zone.

GUSTAVIA RHODANTHA Standl. Colombia: Bolivar: Tierra Alta, on Rio Sinu, *Pennell 4629*. Like the preceding, this species appears to be new to South America, having been otherwise reported only from the San Blas District of Panama.

Eschweilera montana sp. nov. Arbor ad 25 m. alta; ramulis subteretibus juventute striatis fuscis cinereo-puberulis mox glabris et cinereis; foliis glabris, petiolis rugosis superne leviter angulatis 5-6 mm. longis, laminis coriaceis utrinque laevibus siccitate olivaceo-fuscis oblongo-ellipticis, 8-14 cm.

1 Received for publication April 22, 1939.

longis, 3-5.5 cm. latis, basi acutis et petiolo leviter decurrentibus, apice breviter et obtuse acuminatis, margine leviter revolutis et subintegris vel obscure crenulatis, costa utrinque prominente, nervis secundariis utroque 6-9 arcuato-adscendentibus inconspicue anastomosantibus subtus planis et inconspicue immersis subtus leviter elevatis, venulis reticulatis utrinque planis vel obscuris; inflorescentiis terminalibus vel axillaribus paniculatis pauciramosis 3-7 cm. longis praeter rhachidem ramulos et pedicellos molliter cinereo-puberulos glabris; rhachide gracili leviter flexuosa; pedicellis gracilibus 6-10 mm. longis, bracteis bracteolisque mox deciduis; calvce cupuliformi, limbo suberecto, lobis 6 anguste imbricatis oblongo-ovatis 2-3 mm. longis et latis, apice rotundatis; petalis 6 eburneis submembranaceis tenuiter nervatis inaequalibus oblongo-obovatis, sub anthesi 11-14 mm. longis et 6-10 mm. latis, apice rotundatis; androphoro explanato circiter 20 mm. longo, ligula circiter 6 mm. lata, galea 9-12 mm. diametro spiraliter incurvata appendiculis anantheris 3-4 mm. longis dense echinata; staminibus numerosis (circiter 150), filamentis 1-1.3 mm. longis, antheris subglobosis circiter 0.5 mm. diametro; ovario semisupero vertice valde convexo umbonato laevi glabro, loculis 2, ovulis in quoque locula 6-10, stylo anguste conico circiter 1 mm. longo.

Type, Smith 2990, collected January 19, 1938, in dense forest of the Akarai Mountains, on height of land between drainage of Rio Mapuera (Trombetas tributary) and Shodikar Creek (Essequibo tributary), Brazil-British Guiana Boundary, alt. 600-800 m. E. montana belongs to a group of small-flowered species including E. micrantha (Berg) Miers, E. grata Sandwith, and E. floribunda Eyma. From all of these it is readily distinguished by its smooth leaves with more obscure secondaries and veinlets, and from the last, perhaps its closest ally, by its less freely branched inflorescence, glabrous eciliate sepals, and slightly larger petals.

Eschweilera alata sp. nov. Arbor 20–28 m. alta ubique glabra, trunco 15–35 cm. diametro; ramulis

fuscis gracilibus conspicue bialatis (alis subcoriaceis 1-1.5 mm. latis); petiolis crassis rugosis leviter canaliculatis 5-15 mm. longis; laminis coriaceis siccitate fusco-olivaceis oblongo-ellipticis, 15-27 cm. longis, 5-10 cm. latis, basi rotundatis vel obtusis vel subattenuatis et petiolo decurrentibus, apice gradatim breviter acuminatis, margine subintegris vel obsolete crenatis vel conspicue undulatis, costa utrinque prominente, nervis secundariis utroque 9-12 patentibus vel subadscendentibus marginem versus inconspicue anastomosantibus utrinque elevatis, rete venularum crasse intricato utrinque conspicue prominulo; inflorescentiis terminalibus (et axillaribus?) simplicibus 10-15 cm. longis, rhachide gracili (internodiis 1-2 mm. diametro) leviter flexuosa striata 10-15-flora, pedunculo brevi; pedicellis erassis rugosis 8-20 mm. longis distaliter incrassatis, 1-3 mm. supra basin conspicue articulatis, cum calyce (ex coll.) viridibus vel purpurascentibus; calycis tubo turbinato rugoso, lobis 6 patentibus ovatooblongis, 4-5.5 mm. longis et latis, apice rotundatis, margine saepe ciliolatis; petalis 6 eburneis vel basi pallide roseo-purpurascentibus, obovatis, 20-25 mm. longis, 15-25 mm. latis, apice rotundatis, margine fimbriatis; androphoro eburneo explanato 35-40 mm. longo, ligula subcoriacea 12-14 mm. lata, galea 15-20 mm. diametro spiraliter incurvata, parte apicali extus appendiculis 3-5 mm. longis dense echinata; staminibus numerosis, filamentis clavatis 1.3-2.5 mm. longis, apice mucronulatis, antheris oblongis circiter 0.7 mm. longis; ovario subinfero vertice leviter elevato umbonato, loculis 2 multiovulatis, stylo brevi crasso.

Type, British Guiana Forestry Dept. 2564 (D541), collected November 11, 1937, in Morabukea mixed forest near Kumuparu Creek, basin of Demerara River, British Guiana. Another collection from the same locality is Forestry Dept. 2560 (D537). These specimens were kindly sent to me for study by Prof. S. J. Record, and duplicates are deposited in the Yale School of Forestry. The native name is reported as "Guava-skin Kakaralli," in contrast to "Smooth-leaved Kakaralli" (E. decolorans Sandwith), which occurs in the same region.

E. alata is distinguished by its large glossy leaves with coarsely reticulate venation, its simple lax comparatively few-flowered inflorescences, its large flowers with white petals, its coiled androecium, and its 2-celled ovary. It is also characterized by having its branchlets, at least distally, narrowly 2-winged; this character separates it from the allied E. subglandulosa (Steud.) Miers, as do also the coarseness of the veinlet reticulation, the usually longer pedicels, and the larger flowers.

Eschweilera rhododendrifolia (Knuth) comb. nov. Chytroma rhododendrifolia Knuth in Fedde Rep. Sp. Nov. 38: 116. 1935. Krukoff 7991, from essentially the type locality near Manaos, Amazonas, Brazil, is referred to this species with some misgivings, the type not being available to me at present. Compared with the description, our speci-

men is somewhat more robust throughout, with leaf blades proportionately slightly narrower and inflorescences longer. These characters are hardly of specific significance, but the present plant has the ovary 2-celled, whereas Knuth's reference of his plant to *Chytroma* implies a 4-celled ovary, although this is not stated in the description.

Eschweilera conduplicata sp. nov. Arbor ad 20 m. alta ubique glabra; ramulis crassis rugosis demum cinereis inconspicue lenticellatis; petiolis crassis canaliculatis 9-17 mm. longis; laminis coriaceis siccitate olivaceo-viridibus late ellipticis vel leviter oblongo-obovatis, 9-15 cm. longis, 4.5-8 cm. latis, basi rotundatis vel obtusis vel subattenuatis et saepe petiolo decurrentibus, apice rotundato-obtusis vel obtuse et breviter acuminatis, margine leviter recurvatis et subintegris vel obsolete crenatis, inter costam et margines sulculis utroque 2-4 curvatis plerumque signatis, costa supra elevata subtus prominentissima et striata, nervis secundariis utroque 14-18 patulis inconspicue anastomosantibus supra subplanis vel obtuse elevatis subtus prominulis, rete venularum arcte intricato supra plano vel minute prominulo subtus manifeste prominulo; inflorescentiis axillaribus et terminalibus simplicibus vel raro basin versus pauciramosis 11-30 cm. longis, rhachide crassa flexuosa angulata 20-50-flora; pedicellis crassis valde rugosis 1-3 mm. longis persistentibus, basi bracteatis, apice bracteolatis et conspicue articulatis (bracteis bracteolisque caducis non visis); floribus in articulo sessilibus expansis circiter 4 cm. diametro; calyce purpureo, tubo valde verruculoso, lobis 6 margines versus virescentibus coriaceis patulis anguste imbricatis oblongis, 6-8 mm. longis et latis, apice rotundatis; petalis 6 roseis tenuiter carnosis oblongis, 16-20 mm. longis, 11-16 mm. latis, apice rotundatis, margine integris; androphoro carnoso explanato 35-40 mm. longo, ligula 10-15 mm. lata, galea rosea supra ovarium inflexa neque spiraliter incurvata 14-17 mm. diametro, parte inflexa intus appendiculis incrassatis linearibus apicem versus directis echinata; staminibus numerosissimis (300 vel ultra), filamentis complanatis 2.5-4 mm. longis, apice abrupte contractis et filiformibus, antheris luteis subglobosis 0.5-0.7 mm. diametro; ovario subinfero vertice leviter convexo striato-sulcato sub anthesi 3-4 mm. diametro, loculis 4, ovulis in quoque loculo 10-14; stylo carnoso 2-3 mm. longo, stigmate minute 4-lobato, lobis reflexis.

Type, Smith 2332, collected November 1, 1937, in forest in basin of Rupununi River, near mouth of Charwair Creek, latitude about 2°35'N., British Guiana. It is fairly abundant locally along the forest fringes in the upper Rupununi region, apparently occurring not along the river itself, but on the inner edges of the forest near the sharp line of transition to the savanna which covers the major portion of the region. Search in other parts of the Rupununi region did not disclose the species in a second locality. It is a striking and beautiful tree, conspicuous for its rich pink petals and androecia.

E. conduplicata is related to a small group of predominantly Amazonian species with coriaceous leaves, a simple or few-branched long inflorescence with a stout angled flexuose rachis, short-pedicellate or essentially sessile flowers of medium size for the genus, an androecium not coiled inwards but simply bent over the ovary, and a 4-loculed ovary. Among its relatives are  $E.\ rorida$  (Miers) A. C. Smith, E. retusa (Spruce) Nied., and E. ovalifolia (DC.) Nied. From these the new species is distinguished by the conspicuously finer reticulation of its veinlets, by the prominent marks of conduplicate vernation of its leaf blades (perhaps not a stable character but very pronounced in available material), by the larger sepals, and by other details of flower size and texture.

Eschweilera alutacea sp. nov. Arbor ad 25 m. alta ubique glabra; ramulis nigrescentibus vel cinereis crassis rugosis dense lenticellatis; petiolis crassis profunde canaliculatis 4-8 mm. longis; laminis coriaceis siccitate supra fusco-olivaceis subtus brunneis late ellipticis, 12-19 cm. longis, 7-9.5 cm. latis, basi rotundatis vel leviter subcordatis et petiolo abrupte decurrentibus, apice breviter acuminatis, margine subplanis et obsolete crenatis, costa utrinque prominente et striata, nervis secundariis utroque 15-17 patentibus marginem versus arcuatis et inconspicue anatomosantibus utrinque acute elevatis, rete venularum intricato supra leviter prominulo fere plano subtus conspicuo; inflorescentiis axillaribus et terminalibus simplicibus vel basin versus binis 12-19 cm. longis, rhachide crassa (internodiis 2-3 mm. diametro) angulata conspicue lenticellata 25-40-flora, pedunculo subnullo; pedicellis crassis (circiter 3 mm. diametro) 1-2 mm. longis apice conspicue articulatis bracteolatis (bracteolis crasse coriaceis) persistentibus; floribus in articulo sessilibus expansis 5-6 cm. diametro; calycis tubo valde rugoso sub anthesi 3-4 mm. longo et 7-9 mm. diametro inconspicue lenticellato, lobis 6 coriaceis ovato-oblongis, 10-12 mm. longis, 8-10 mm. latis, apice rotundatis, margine saepe obscure glandulosis; petalis 6 albidis tenuiter carnosis oblongo-obovatis, 25-30 mm. longis, 13-23 mm. latis, apice rotundatis, margine saepe glanduloso-ciliolatis; androphoro albido distaliter flavido explanato 50-55 mm. longo, ligula 11-15 mm. lata, galea supra ovarium inflexa neque spiraliter incurvata 20-25 mm. diametro, parte inflexa valde incrassata intus appendiculis ad 10 mm. longis patentibus dense echinata; staminibus numerosissimis (200 vel ultra), filamentis clavatis 3-4 mm. longis, apice mucronulatis, antheris luteis oblongo-subglobosis circiter 0.6 mm. diametro; ovario subinfero vertice plano vel leviter convexo plurisulcato, loculis 4, ovulis in quoque loculo 10-12; stylo carnoso cylindricoconico 4-5 mm. longo, stigmate minute 4-lobato.

Type, Smith 2690, collected December 17, 1937, in dense forest along Essequibo River, near mouth of Onoro Creek, latitude about 1°35'N., British Guiana. E. alutacea is characterized by broad thick

short-petioled leaves, long stout inflorescences, large subsessile flowers with white petals and a yellowish androecium, a 4-loculed ovary, and an androecium simply bent over the ovary but not coiled inwards. It belongs in the same general alliance as the preceding (E. conduplicata) and its allies, but is more robust throughout and differs in flower color, apparently a dependable character in the genus. A nearer relationship is with E. holcogyne Sandwith, from which it differs by its substantially larger leaves with more numerous secondaries, much longer and more robust inflorescence, broader sepals and petals, and longer style. Perhaps a closer ally, according to the description, is Eschweilera Miersii (Knuth) A. C. Smith. comb. nov. (Chytroma Miersii Knuth in Fedde, Rep. Sp. Nov. 38: 114. 1935), from which E. alutacea differs by its short petiole, thicker leaves with more spreading secondaries, shorter and much slenderer rachis, and much smaller calyx tube.

Eschweilera confertiflora sp. nov. Arbor ad 31 m. alta, rhachidibus, pedicellis, et saepe basin versus calycibus cinereo-puberulis exceptis glabra, trunco circiter 30 cm. diametro; ramulis teretibus cinereis gracilibus; petiolis nigrescentibus striatis canaliculatis superne anguste alatis 3-6 mm. longis; laminis tenuiter coriaceis siccitate fuscis oblongoellipticis 5.5-8 cm. longis, 2-3.5 cm. latis, basi acutis, apice breviter cuspidatis et calloso-apiculatis, margine subintegris vel obsolete crenatis, costa utrinque valde elevata, nervis secundariis utroque 11-13 rectis patentibus marginem versus anastomosantibus cum rete venularum arcte intricato utrinque valde prominulis; inflorescentiis axillaribus et terminalibus simplicibus 8-13 cm. longis, rhachide crassa (internodiis circiter 2 mm. diametro) angulata lenticellata 45-55-flora, pedunculo subnullo; pedicellis 3-5 mm. longis 1-3 mm. supra basin conspicue articulatis, bractearum cicatricibus conspicuis, bracteolis caducis; pedicellis apicem versus et calveis tubo valde verruculosis; sepalis 6 oblongoovatis, circiter 3 mm. longis et 2 mm. latis, apice rotundatis; petalis 6 submembranaceis oblongo-obovatis, 8-12 mm. longis, 6-8 mm. latis, apice rotundatis; androphoro explanato circiter 15 mm. longo, ligula circiter 5 mm. lata basi expansa, galea supra ovarium inflexa neque spiraliter incurvata 7-9 mm. diametro, parte inflexa intus appendiculis ad 2 mm. longis deorsum (basin versus) directis dense echinata; staminibus numerosis, filamentis ligulatis vel clavatis 1.5-3.5 mm. longis, apice mucronulatis, antheris subgloboso-oblongis 0.4-0.5 mm. diametro; ovario subinfero vertice leviter elevato et obscure plurisulcato, loculis 4, ovulis in quoque loculo 3-5; stylo subulato carnoso circiter 2.5 mm. longo; pyxidio immaturo valde lenticellato turbinato, vitta interzonali suberecta, sepalis persistentibus, operculo leviter convexo conspicue apiculato.

Type, British Guiana Forestry Dept. 2557, collected November 5, 1937, in climax forest along Kumuparu Creek, basin of Demerara River, British

Guiana. The specimen was kindly forwarded to me for study by Prof. S. J. Record, and a duplicate is in the herbarium of the Yale School of Forestry (serial no. 35448). Unfortunately the flower color is not recorded, but in dried condition the petals have a pinkish tinge. E. confertiflora is distinguished by an unusual combination of characters; it has small coriaceous leaves with densely reticulate and strongly prominulous veinlets, long stout angled simple puberulent many-flowered inflorescences, short pedicels conspicuously articulate near the middle, comparatively small flowers, an androecium bent over the ovary but not spirally incurved, and a 4-celled ovary. It appears to be without close relatives, but may be compared, among Guiana species, to E. corrugata (Poit.) Miers, E. chartacea (Berg) Eyma, E. Wachenheimii (Ben.) Sandwith, and E. praeclara Sandwith, from all of which it is distinguished by its leaf size and venation and its inflorescence characters.

BERTHOLLETIA EXCELSA H. B. K. British Guiana: basin of Shodikar Creek (Essequibo tributary), latitude about 1°18'N., Smith 2868. The species is fairly abundant in this locality, where it was in good flowering condition in January and also bearing maturing fruits of the previous year. It is said to be a dominant tree farther north near King William's Falls on the middle Essequibo and also in the upper Corentyn region.

COURATARI TENUICARPA A. C. Smith. Since this species was originally described on the basis of a fruiting specimen from the basin of Rio Madeira, it has been collected in good flowering condition (Ducke 497, from Rio Taruma, near Manaos, Amazonas, Brazil). The following notes should be considered in connection with the original description:

Inflorescentiae ubique (i.e. rhachide, pedicellis, bracteis, calveibus, sepalis, et petalis extus) dense cinereo- vel fusco-puberulae; racemis e ramulis efoliatis ut videtur saepe orientibus simplicibus 7-15 cm. longis; rhachide gracili subtereti 10-20flora; pedicellis gracilibus 11-22 mm. longis, bracteis papyraceis oblongis 3-4 mm. longis subtentis; sepalis 6 anguste imbricatis semiorbiculari-ovatis, 1.5-2 mm. longis, 2-3 mm. latis, apice rotundatis, margine fimbriatis; petalis 6 membranaceis glabrescentibus tenuiter nervatis oblongo-obovatis, 17-22 mm. longis, 7-11 mm. latis, basi angustatis, apice rotundatis, margine integris et fimbriatis; androphoro glabro explanato 17-20 mm. longo, ligula 5-7 mm. lata, galea 6-8 mm. diametro laevi; staminibus circa annulum circiter 20, filamentis gracilibus 0.3-0.4 mm. longis, antheris transversaliter ovoideis circiter 0.5 mm. longis et 0.7 mm. latis; ovario turbinato vertice leviter convexo et glabro umbonato; stylo brevi crasso; loculis 3, ovulis 15-20 in quoque loculo.

Couratari reticulata sp. nov. Arbor sub fructu ubique glabra 35 m. alta, trunco 80 cm. diametro; ramis ramulisque teretibus purpurascentibus juventute striatis; petiolis canaliculatis anguste alatis

7-12 mm. longis; laminis subcoriaceis ellipticis siccitate fusco-olivaceis, 11-15 cm. longis, 5-8 cm. latis, basi obtusis et petiolo abrupte decurrentibus, apice subacutis vel breviter obtuse acuminatis, margine inconspicue undulato-crenatis, costa utrinque prominente, nervis secundariis utroque 16-22 utrinque elevatis 5-10 mm. intra margines conspicue anastomosantibus, venulis copise et conspicue reticulatis utrinque valde prominulis; pyxidio obconicocylindrico vix trigonoideo 7-10 cm. longo zona calveari prominente 4-5 cm. diametro cincto, vitta interzonali erecta vel paullo convexa 5-10 mm. alta; operculo laevi circiter 3.5 cm. diametro, columella acute triquetra; pericarpio brunneo coriaceo circiter 1 mm. crasso extra laevi et dense lenticellato intus septorum 3 vestigiis signato; seminibus in quoque loculo circiter 4 elliptico-obovatis, circiter 5 cm. longis et 2.2-2.8 cm. latis, scuto embryonifero centrali ad 3.5 cm. longo et 1 cm. lato ala membranacea cincto.

Type, Smith 3561, collected April 13, 1938, in dense forest on northwestern slopes of Kanuku Mountains, in drainage of Moku-moku Creek (Takutu tributary), altitude 200 m., British Guiana. It is a tree with a straight trunk and small inconspicuous buttresses. Flowers of the new species are lacking, and unfortunately only one attached fruit containing seeds could be found, although the felled tree was thoroughly searched. Several old fruits were obtained from the ground. On foliage and fruit characters, C. reticulata can be readily distinguished, being characterized by hard elliptic leaves with crenulate margins and closely reticulate venation, firm smooth fruits of medium size for the genus, and broadly elliptic seeds. It appears to be not closely related to other Guiana species, but on the basis of its fruits to suggest C. glabra Camb. of southern Brazil. However, the leaves of that species are oblong-lanceolate, smaller, and much narrower than those of the new species, while the pyxidium is slightly different in proportions, with a higher interzonal band.

Couratari stellata sp. nov. Arbor excelsa praeter inflorescentiam ubique glabra ad 30 m. alta, trunco 50 cm. diametro; ramis ramulisque teretibus juventute purpurascentibus striatis conspicue lenticellatis mox cinereis; petiolis subcomplanatis alatis 5-10 mm. longis alis inclusis 3 mm. latis; laminis tenuiter coriaceis ellipticis, 6-10 cm. longis, 3-5.5 cm. latis, basi attenuatis petiolo decurrentibus, apice breviter (2-4 mm.) cuspidatis, margine crenatoserratis (serrationibus 5 vel 6 per centimetrum), sulculis curvatis longitudinalibus inconspicue signatis, costa supra elevata subtus prominente, nervis secundariis utroque 13-16 utrinque valde prominulis 5-7 mm. intra margines anastomosantibus, venulis copiose et conspicue reticulatis utrinque prominulis; racemis axillaribus et terminalibus simplicbus 10-15 cm. longis utrinque (i.e. rhachide, pedicellis, calycibus, sepalis, et petalis extus) dense et arcte fusco-stellato-tomentellis (pilis 6-12-ramosis sessilibus circiter 0.2 mm. longis); rhachide angulata 12-20-flora; pedicellis 4-7 mm. longis, basin versus bracteolarum cicatricibus 2 conspicuis signatis: sepalis 6 imbricatis semiorbiculari-ovatis, 4-5 mm. longis, 6-7 mm. latis, basi auriculatis. apice rotundatis vel mucronulatis, margine saepe fimbriatis; petalis 6 siccitate papyraceis valde concavis obovatis, 20-25 mm. longis, 18-22 mm. latis, intus glabris, obscure nervatis, basi angustatis, apice rotundatis, margine minute serrulatis vel erosis; androphoro glabro explanato circiter 30 mm. longo, ligula circiter 10 mm. lata, galea 8-12 mm. diametro utringue dense echinata, appendiculis lineari-subulatis ciliatis; staminibus circa annulum 40-45, filamentis 0.5-0.8 mm. longis, antheris oblongis circiter 1 mm. longis; ovario rugoso turbinato vertice plano et pubescente; stylo crasso circiter 1 mm. longo; loculis 3, ovulis 30-35 in quoque loculo; pyxidio cylindrico-conico saepe falcato, 5-6 cm. longo, zona calvcari 2.2-3 cm. diametro leviter elevata, vitta interzonali erecta 3-6 mm. alta; operculo laevi 2-2.5 cm. diametro centro abrupte depresso, columella acute triquetra; pericarpio laevi circiter 1 mm. crasso extra dense lenticellato; seminibus compressis oblongo-obovatis, scuto embryonifero centrali ala membranacea lata cincto.

Type, Krukoff 8893, collected October-December, 1936, on terra firma in high forest in basin of Creek Belem, Municipality São Paulo de Olivença, basin of Rio Solimoes, Amazonas, Brazil. C. stellata is quite distinct, on the basis of foliage and inflorescence, from any described species. It is characterized by winged petioles, finely reticulate leaf blades with crenate-serrate margins, simple racemose inflorescences, and dense close stellate pubescence of flower parts. In inflorescence characters it shows a relationship with C. macrosperma A. C. Smith, but that species, as well as the closely allied C. Krukovii A. C. Smith, is much more robust in all its parts. The pyxidium of the new species suggests that of C. paraensis Mart., otherwise unknown. It seems advisable to describe the present species as new rather than to tie it to such a poorly defined name, especially since the two plants are from very different localities.

Couratari oligantha sp. nov. Arbor; ramulis gracilibus teretibus juventute fuscis minute puberulis mox cinereis glabris; petiolis gracilibus striatis decidue puberulis superne anguste alatis 5-8 mm. longis; laminis papyraceis praeter costam supra interdum inconspicue puberulam glabris, oblongoellipticis, 7-11 cm. longis, 2-4.5 cm. latis, basi angustatis et petiolo decurrentibus, apice gradatim acuminatis (acumine ad 1 cm. longo subacuto), margine subintegris, costa supra acute elevata subtus prominente, nervis secundariis utroque 7-10 arcuato-adscendentibus marginem versus anastomosantibus cum rete venularum intricato utrinque prominulis; racemis terminalibus et axillaribus 3-6floris ubique (rhachide, bracteis minutis caducis, pedicellis, calveibus, et petalis) arcte et dense cinereo-puberulis; rhachide gracilibus ad 2.5 cm. longis; pedicellis gracilibus curvatis 15-25 mm. longis prope basin articulatis; calycis tubo sub anthesi cupuliformi circiter 3 mm. longo et 4–5 mm. diametro, sepalis 6 patentibus anguste imbricatis deltoideo-ovatis, 5–6 mm. longis, 4–5 mm. latis, apice obtusis vel rotundatis, margine ciliolatis, intus parce puberulis; petalis 6 submembranaceis venuste nervatis intus glabris, oblongis vel anguste obovatis, 20–30 mm. longis, 7–12 mm. latis, apice rotundatis, margine ciliolatis et distaliter erosis; androphoro glabro explanato 20–25 mm. longo, basi late expanso, ligula 6–8 mm. lata, galea circiter 8 mm. diametro non echinata; staminibus circiter 50, filamentis gracilibus circiter 0.5 mm. longis, antheris subglobosis circiter 0.7 mm. diametro; ovario vertice leviter elevato umbonato, stylo brevi crasso.

Type, Louis Weiss & Hermann Schmidt 1, collected in 1907 or 1908 in the region of the upper Rio Negro, Amazonas, Brazil. The local name "Tauary" is recorded; it is unfortunate that no detailed locality or habitat data are available. The slender puberulent few-flowered inflorescences with long pedicels and large flowers readily separate C. oligantha from the others of the genus. The leaves are also extremely distinct, being smaller than those of most species, narrow, and gradually taper-

ing at both ends.

Cariniana pachyantha sp. nov. Arbor excelsa ubique glabra ad 37 m. alta, trunco circiter 50 cm. diametro; ramulis crassis nigrescentibus teretibus parce lenticellatis; petiolis crassis (circiter 3 mm. diametro) canaliculatis superne anguste alatis 5-8 mm. longis; laminis tenuiter coriaceis vel papyraceis siccitate olivaceo-viridibus ovato-oblongis, 9-13 cm. longis, 5-9 cm. latis, basi rotundatis et subito petiolo decurrentibus, apice abrupte acuminatis (acumine gracili 7-12 mm. longo), margine integris et anguste revolutis, costa supra leviter elevata vel subplana subtus prominente, nervis secundariis utroque 13-19 rectis patulis 3-10 mm. distantibus marginem versus abrupte adscendentibus utrinque leviter elevatis, venulis subimmersis creberrime transversis; inflorescentiis axillaribus vel terminalibus paniculatis 6-12 cm. longis multifloris, ramulis numerosis angulato-striatis transverse rugosis; floribus sessilibus; calvcis tubo turbinato sub anthesi 1-2 mm. longo et 2-3 mm. diametro, limbo erectopatente, lobis 5-7 crasse carnosis deltoideis circiter 1 mm. longis et 1.5 mm. latis apice obtusis; petalis 5-7 crasse carnosis valde imbricatis concavis integris oblongo-obovatis, 5-6 mm. longis, 2-3.5 mm. latis, apice rotundatis; androphoro breviter tubuloso crasse carnoso oblique truncato 2.5-3 mm. alto in laciniis antheriferis abeunte; staminibus 17-25, filamentis valde reflexis 0.5-0.8 mm. longis distaliter abrupte contractis, antheris transversaliter ellipsoideis circiter 0.4 mm. longis et 0.6 mm. latis; ovario vertice plano vel leviter convexo, loculis 3, ovulis in quoque loculo 10-12; stylo carnoso circiter 0.4 mm. longo truncato.

Type, Krukoff 8690, collected October-December, 1936, in high forest on terra firma in basin of Creek Belem, Municipality São Paulo de Olivença,

basin of Rio Solimoes, Amazonas, Brazil. C. pachyantha is clearly related to C. uaupensis (Spruce) Miers, being hardly distinguishable on inflorescence characters. The new species is characterized by its much shorter petioles and differently shaped leaf blades, which are more definitely truncate at base and nearly as broad as those of C. uaupensis, although hardly half as long. The older species has 22-27 pairs of secondary nerves. C. multiflora Ducke (represented in the present collection by Krukoff 8164, 8508, and 8624 from essentially the

type locality) is more distantly of this relationship. Cariniana Micrantha Ducke. This species, originally described in 1930 and known from several localities in the basins of the Amazon, Tapajoz, Madeira, Jurua, and Purus, is now represented from the Solimoes by Krukoff 8796. C. clavata Novik. (Acta Inst. Bot. Acad. Sci. URSS I. 2: 250. f. 2. 1936) from Amazonian Colombia, described and figured from fruit only, is certainly the same species

NEW YORK BOTANICAL GARDEN

#### SEX INTERGRADES IN DIOECIOUS MAIZE 1

Donald F. Jones

THE UNISEXUAL maize plants, described previously (Jones, 1934), have been continued five additional generations. These later investigations bring out clearly the fact that the floral expression varies in different families and that this variation is under germinal control. The original dioecious condition was established by combining two recessive characters known as silkless (sk) and tassel seed  $(ts_2)$ in such a way that sk sk ts2 ts2 constituted the female plants and sk sk Ts2 ts2 the male plants. Thus the females are homozygous and the males heterozygous for the Ts2 ts2 locus on chromosome 1. It was also shown that other modifying factors influenced the floral expression such that some female plants showed varying numbers of staminate parts and that some male plants showed an occasional pistillate floret.

The general conclusion from this preliminary study was stated as follows: "One specific gene holds the balance of control over the sex of the offspring. In its action this gene is wholly dependent upon the support of at least one other gene located in a different chromosome. Other genes working with physiological modifiers, both internal and external, influence the development of the sex organs and bring about varying degrees of intergradation between the two sexes. None of these factors has been specifically located, but definite evidence for their existence is at hand. They are complex in their action and widely distributed in the chromosomes." The present report is concerned with some of these internal and external influences that bring about varying expression of the floral mechanisms.

Of the original 14 families, three were selected for further propagation and study. These are numbers 4, 6, and 10. Family 4 showed the least tendency to produce anthers in the terminal inflorescences. Families 6 and 10 produced female plants with a strong tendency to develop male parts both in the terminal inflorescences of the female plants and in the lateral inflorescences of the male plants. Family 6 was cross-pollinated with family 5 and family 10 with 6. All three families were closely

1 Received for publication February 18, 1939.

alike in appearance and in the degree of sex-intergradation. Following this original crossing, the progenies have resulted from matings within the family. Number 4 has been mated within the family from the beginning. Families 6 and 10 showed somewhat more vigor in the first two or three generations following the crossing of these related lines, but in the later generations the plants have made no larger growth than family 4.

The behavior of these three families during five generations is shown in table 1. An arbitrary scale was devised with which to classify the female plants ranging from 0 to 9, depending upon the number of florets in the terminal inflorescence having anthers. In the zero grade all of the flowers are pistillate with no anthers. In grade 1 the florets at the tip of the main spike have a few aborted anthers but do not produce functional pollen. Grade 2 produces a small quantity of functional pollen, and the higher grades have an increasing proportion of anthers and a gradually decreasing number of stigmas up to a complete change of the female to the male condition in the terminal inflorescence.

Before 1935 the female progenitors of these dioecious families were selected for a low grade of terminal inflorescence, either 0 or 1. In 1935 it was noted that families 6 and 10 had a tendency to produce a higher proportion of anthers in the female plants than the others. From then on plants of a high grade, from 5 to 9, were selected as progenitors. Thus families 6 and 10 were selected during three generations for a high degree of sex-intergrades, while family 4 was continued to be selected for a low degree. The result is shown in table 1. There is a slight shift upward in the number and degree of female plants with male tendencies in families 6 and 10. Family 4 on the other hand remained approximately the same throughout the fiveyear period.

The important point is the pronounced difference in degree and variability of intersexuality in the three families. Since they came from the same original plants and have been grown continuously under the same environmental conditions, the con-

clusion is obvious that the determining factors are within the plants themselves and associated with the transmissible heredity.

The male plants also have shown a tendency to vary. This is expressed in the usually sterile lateral inflorescence. As illustrated and described in the previous report (Jones, 1934), these lateral inflorescences occasionally produce a few abortive stigmas. Rarely do these extend beyond the enclosing husks (bracts) and are therefore seldom fertilized. In a few cases seeds are produced. When the husks are spread apart and pollen is applied to these poorly developed stigmas, seeds are sometimes formed.

Other plants produce anthers at the tips of these sterile female inflorescences. The anthers never contain well-formed pollen and even when exposed to the air do not dehisce. Stigmas and anthers have never been found in the same lateral inflorescence in these families. In table 2 the three families are compared in the number of male plants that have male or female tendencies in the lateral inflorescences. Family 4 produces a large proportion of female intergrades and no male intergrades. Families 6 and 10, in contrast, produce few individuals with female tendencies and a slightly larger number with male tendencies. Thus the family with the greatest tendency towards femaleness in the female plants also has the most tendency towards femaleness in the male plants. There is therefore a decided shift towards femaleness in this family. In the other two families the shift is in the opposite direction. Both males and females show more male characters.

This is proof that there are modifying factors which govern the expression of the two main sex-differentiating loci. Whether these are carried in the chromosomes or in some other place cannot be

determined from the results obtained so far. Since they segregated at random in the early generations and responded to selection in the later generations, they are presumably in the chromosomes.

The five growing seasons including 1934 and 1938 were characterized by considerable variation in rainfall and temperature. The first three years were drier than normal during some part of the summer, and plants suffered considerably. In 1937 the season was generally favorable. The plants made a luxuriant growth and yielded well. In 1938 the first part of the season was excessively wet and cool. There was much leaching, and plants suffered

from nitrogen starvation during the later part of the season. The plants in family 4 responded approximately the same to all five seasons. There is a slight shift upward in grade of the terminal inflorescence but not of the same order as in families 6 and 10 where there was a response to selection. The same situation is apparent in table 2 where seasonal fluctuations had no noticeable effect. This is evidence that sex expression in these families of dioecious maize is influenced relatively little by the fluctuations of their normal environment as it may vary in rainfall, temperature, and fertility.

It is also clear from table 3 that sex expression in these plants is not influenced by hybrid vigor. In family 4 eight progenies were grown in 1938 from parental plants that had been mated within the same line by sib-pollinations. Eight other progenies from the same lines were grown from seed that had been intercrossed between different lines, all within the same family. The intercrossed progenies were taller and more vigorous, but there is no difference in the grade of the female plants. These two lots were grown in alternating rows. Since hybrid vigor has much the same effect upon plants as better environmental conditions, this is additional evidence that, in these plants, sex expression is independent of the usual environmental deviations.

Sharp (1934) and Loehwing (1938) have reviewed investigations dealing with external effects upon sex expression in plants. There is much evidence to show that nutritional and other environmental agencies have a modifying influence but only when these changes are extreme. In the normally fluctuating environment these dioecious maize plants are relatively free from external modification and show clearly the action of internal determiners capable of meiotic recombination.

The total number of female, male, and normal monoecious plants is given in table 1. The totals include some plants that could not be classified as to grade due to smut infection or other causes of incomplete development of the terminal inflorescences. As explained in the previous publication, it is not possible to distinguish between female plants which are homozygous sk sk and those which are heterozygous Sk sk. The latter will continue to give some normal bisexual plants. Any outcrossing with unrelated plants will also give normal individuals. Usually these can be detected on account of their larger size. In families 6 and 10 the upper grades of the female plants approach the normal condition and undoubtedly some of the plants classified as hermaphrodites are females that are completely changed to males in the terminal inflorescence. Such plants should still be homozygous silkless, but so far no plants have been identified by testing.

In the three families, 4, 6, and 10, several progenies were grown each year from pollinations of individual female by individual male plants. In 1934 two out of four progenies in family 4 produced no normal hermaphrodites. In 1938 all the 16 progenies grown contained no plants of this type with the exception of one tall vigorous plant that was clearly an outcross. In families 6 and 10 a considerably larger number of hermaphrodites appeared, but some progenies produced none. In 1937 seven female plants in as many different progenies of family 4 were outcrossed by the original silkless strain. The resulting F<sub>1</sub> plants, 140 in all, were completely silkless with normal tassels. Three progenies in family 6 were tested in the same way and produced only silkless plants. Apparently most of the heterozygous Sk sk individuals have been eliminated. If this is true, the progenies that are free from hermaphrodites should remain so providing accidental outcrossing can be prevented.

There has been no significant change in the sexratio during the nine generations this dioecious corn has been continued. As reported in the previous publication, the ratio based on all progenies free from hermaphrodites was 1 male to 1.24 females. From 1934 to 1938 the ratio in family 4 was 1 to 1.14, based on 656 individuals. This same family in 1938 with no hermaphrodites produced 138 males and 168 females, a ratio of 1 to 1.22. The constant excess of females over males cannot be accounted for. There are no visible differences in the chromosomes and no apparent reason why a gamete carrying a chromosome with recessive  $ts_2$  should have any competitive advantage over its homolog carrying the dominant male-determining allele.

#### SUMMARY

Three families of dioecious maize, originating from a combination of known mutant types, have been propagated for nine generations. All families produce some individuals with a varying degree of male characteristics in the female plants and female characteristics in the male plants.

The families differ in the number and character of these sex-intergrades and respond to selection.

Sex expression in this material is relatively uninfluenced by the normally fluctuating environment and appears to be governed by internal factors capable of segregation and recombination.

## A NEW GROWTH SUBSTANCE, β-NAPHTHOXYACETIC ACID 1

#### S. C. Bausor

MANY SYNTHETIC, hormone-like substances possessing properties that regulate growth and development of plants have been described recently by workers of the Boyce Thompson Institute and others (Zimmerman and Hitchcock, 1937; Zimmerman and Wilcoxon, 1935; Wilcoxon, 1937; Nicol, 1938; Boycen Jensen, 1936; Went and Thimann, 1937; et al.). Among these was α-naphthalene acetic acid which was found to have approximately the same physiological potentialities in causing growth curvatures as 3-indole acetic acid, although Avery et al. (Zimmerman and Hitchcock, 1937) and Thimann and Bonner (1938) showed it to be much less efficient when tested by the Avena coleoptile method. Moreover, its efficiency in inducing root formation on intact plants and cuttings was shown to be greater than that of 3-indole acetic acid (Zimmerman and Hitchcock, 1937). Likewise, a-naphthalene-aceto-nitrile proved physiologically effective, although slower than a-naphthalene acetic acid in its action, but  $\beta$ -naphthalene acetic acid was only slightly active. Acenaphthene acetic acid also showed growth promoting properties (Zimmerman and Wilcoxon, 1935; Nicol, 1938).

MATERIALS AND METHODS.—For the present study the growth-regulating properties of  $\beta$ -naphthoxyacetic acid were tested by applying various concentrations of the material in anhydrous lanolin paste to stems and leaves of intact experimental plants. The substance readily goes into solution in lanolin with gentle heating. The following species were used:  $Ocimum\ Basilicum\ L.,\ Mimosa\ pudica$ ,

<sup>1</sup> Received for publication March 10, 1939.

L., Eranthemum nervosum, R. Br., and Lycopersicum esculentum, Mill. Two groups of control plants were used, one treated with lanolin to which nothing was added and the other with a lanolin paste containing 3-indole acetic acid.

Cuttings of Coleus Blumei, Benth., and Taxus cuspidata, Sieb. & Zucc., were treated with aqueous solutions of  $\beta$ -naphthoxyacetic acid and then planted in a sand bed.

Synthesis of  $\beta$ -naphthoxyacetic acid.—The naphthyl ethers are readily formed from naphthol and an alkyl halide (Taylor, 1930; Gilman, 1938):

In the preparation of  $\beta$ -naphthoxyacetic acid,  $\beta$ -naphthol and monochloracetic acid were refluxed in an aqueous solution of sodium or potassium hydroxide. The following is a typical experiment.

Fifty grams of  $\beta$ -naphthol were dissolved in 450 cc. of water containing 24 grams of KOH. In another flask, 32.7 grams of chloracetic acid were dissolved in 250 cc. of water containing 24 grams of KOH. A slight excess of hydroxide was thus used in each case. The two solutions were mixed together,

shaken, and refluxed for one hour. On cooling, a copious precipitate of potassium  $\beta$ -naphthoxyacetate came out of solution. This is only slightly soluble in water or alcohol and can be purified easily. It was converted to the acid by dissolving in acid alcohol and precipitating by dilution with water. In a typical experiment 4 grams of sodium  $\beta$ -naphthoxyacetate were added to 50 cc. of alcohol and shaken. To the slush thus formed, 10 cc. of 5 per cent sulphuric acid in water were added and the precipitate dissolved. Then 30 cc. more of 5 per cent  $H_2SO_4$  were added, making 40 cc. in all. By adding 250 cc. of water,  $\beta$ -naphthoxyacetic acid was precipitated. The yield, calculated on the basis of  $\beta$ -naphthol, is about 55 per cent of the expected.

The melting point of  $\beta$ -naphthoxyacetic acid is

154-156°C.

It might be noted here that both the sodium and potassium salts were found active as growth-regu-

lating substances also.

EXPERIMENTAL RESULTS.—In recording the results, curvatures produced by unilateral application of the lanolin pastes are termed positive when bending is toward the place of application, and negative when away from it, the assumption being that the latter indicates a stimulating effect and the former an inhibiting one (Went and Thimann, 1937).

Stem reactions of Ocimum Basilicum.—Applied to one side of the stem of Ocimum Basilicum a 1 per cent solution of naphthoxyacetic acid in anhydrous lanolin produced strong positive curvatures at the end of 24 hours, but this concentration proved toxic to the tissues it contacted, causing a brown flaccid necrosis at this place. The leaves wilted and turned brownish-black. This toxic effect was very conspicuous about three days after the application. Below the point where the paste was placed, an abundance of roots appeared, in many cases, down to the basal internode. The root primordia were visible as white bulges in about a week.

With a 0.1 per cent paste, applied in the same way, the stems also curved positively, but showed no evidence of toxic effects. In seven days an abundance of roots had developed, not only below the point of application, but also at the place of contact. The rooting response was more active with the 0.1 per cent paste than with the 1 per cent. It appeared that the rooting response with the higher concentrations, which always occurred below the point of contact, came about by dilution of the naphthoxyacetic acid as it diffused downward.

A 1 per cent lanolin paste of 3-indole acetic acid produced none of the toxic symptoms of  $\beta$ -naphthoxyacetic acid. It caused negative curvatures when applied to the stems, and the root-inducing effects were confined to the area contacted by the paste.

The stems curved negatively when a 0.015 per cent paste was used, but at this concentration no roots developed later. At a concentration of 0.001 per cent no effects were observed.

Leaf reactions of Ocimum Basilicum.—When 1 per cent  $\beta$ -naphthoxyacetic acid in lanolin was applied to the upper or lower sides of the petioles, slight positive curvatures resulted in 24 hours which became more pronounced after three days. When a plant was decapitated at a node and the paste applied in the axil of one of the opposite leaves, the treated leaf curved upward positively (hyponasty) and in three days was almost vertical in position. The opposite leaf showed no effect.

The reaction of the petioles was less definite when a 0.1 per cent paste was used but was essentially like that obtained with the 1 per cent paste.

When a 0.1 per cent paste was applied to the blade of the leaves, no curvature of the petioles resulted in three days. In an experiment in which half of the lower surface of the blade was coated, a positive curvature of the petiole was noted eight days after application. In addition to the down-bending of the petiole, the internode below showed a positive curvature also, and on the side of the petiole corresponding to the side of the lamina on which the lanolin was smeared, three root primordia developed.

Slight negative curvatures resulted in 24 hours when a 0.015 per cent concentration of the paste was applied to either the upper or lower side of the petiole. A 0.001 per cent paste showed no effect.

The basil plants upon which these experiments were performed were about eight inches tall and

grown in pots.

Stem reactions of Mimosa pudica.—A 1 per cent lanolin paste of naphthoxyacetic acid applied to one side of the apical peduncle, on which the flowers had not expanded, produced a strong positive curvature of the apex when observed three and one-half hours after treatment. In 24 hours the curvature was still greater. Two additional peduncles, one at the first node and the other at the second node from the apex, curved downward, although not contacted by the paste. A 0.1 per cent paste similarly applied to an apical peduncle also resulted in a strong positive curvature of the apex. When 0.015 per cent was used, a very slight negative curvature resulted which was not noticeable after three days. No reactions followed treatment with 0.001 per cent.

When a 1 per cent paste was applied to a peduncle with expanded flowers, a strong positive curvature was produced, while pastes containing 0.1, 0.015, and 0.001 per cent, when similarly applied to peduncles bearing open flowers, produced small negative curvatures. It is interesting to note that the peduncle of *Mimosa* was the only organ tested which reacted to a concentration as low as 0.001 per cent.

In no case did rooting occur in Mimosa as a result of these treatments.

Leaf reactions of Mimosa pudica.—A 1 per cent lanolin paste of naphthoxyacetic acid applied to the lower side of the petiole of an unexpanded leaf—but not at the pulvinus—resulted in a strong positive curvature. When the experiment was termi-

nated after nine days, this leaf was dying, indicating that the material was toxic. On the other hand, a 0.1 per cent concentration produced very strong negative curvatures in the petioles of unexpanded leaves, and similar negative curvatures were observed with a 0.015 per cent paste three and one-half hours after application, but the curvature disappeared after 24 hours when the next observation was made. A 0.001 per cent paste showed no effect on the petioles of unexpanded leaves.

When a 1 per cent lanolin paste was applied to the upper side of the pulvinus of a mature leaf, there was no apparent effect. However, on stimulating the leaf by touching it, the leaflets folded together normally, but the petiole did not respond by dropping. This effect remained the same during nine days of observation. A similar effect was produced with a concentration of 0.1 per cent and persisted for several days. But at the end of the nine days' duration of the experiment, the petiole dropped permanently. Concentrations of 0.015 and 0.001 per cent similarly applied to pulvini of mature leaves had no effect on the normal response of the leaves.

When applied to the upper or lower sides—not at the pulvini—of petioles of mature leaves, no effects were produced by concentrations of 0.1, 0.015, and 0.001 per cent, and the leaves responded normally to stimulation.

No effects other than necrosis resulted when the lanolin pastes were applied directly to either the upper or lower surfaces of the apical leaflets.

Burkholder and Pratt (1936) described the effect of 3-indole acetic acid upon Mimosa leaves. They reported that the petioles moved upward and the leaflets remained closed when a lanolin paste of a small concentration of 3-indole acetic acid was applied to the lower surface of the pulvinus and that the petiole moved downward and the leaflets remained open when the paste was located on the upper side.

Reactions of Eranthemum nervosum.—Both 1 and 0.1 per cent pastes of  $\beta$ -naphthoxyacetic acid in lanolin applied to the under surface of the petiole of the leaf caused that organ to curve downward, reaching a maximum curvature about the third day. The internode below the treated leaf was affected also and curved negatively, assuming that the material diffused down the stem on the same side to which the leaf was attached—i.e., it curved away from the leaf. 0.015 and 0.001 per cent pastes had no effect when applied in the same way.

In another series of experiments, the pastes were smeared on one-half of the upper surface of the lamina of the leaf on one side of the midrib. With a concentration of 1 per cent the petiole curved downward and bent horizontally away from the treated side of the blade. The blade itself showed no obvious effects. A 0.1 per cent paste produced a similar reaction but much less pronounced, while both 0.015 per cent and 0.001 per cent pastes were inert.

Reactions of Lycopersicum esculentum.—Only a few tomato plants were available at the time these experiments were performed, but the few trial runs induced the following responses to  $\beta$ -naphthoxy-acetic acid; when a 1 per cent lanolin paste was applied to the stem, it caused a strong positive curvature and epinasty of the leaves. Root primordia later appeared in great abundance in large swollen areas along the stem. A dilute aqueous solution applied to the soil caused an epinastic response of the leaves followed by induction of root primordia similar to the response described by Hitchcock and Zimmerman (1935) for a-naphthalene acetic acid, etc.

A lanolin paste of sodium naphthoxyacetate (saturated) applied to the stem caused a negative curvature and epinasty. It is interesting to note that the action of the salt is slow as compared to that of the acid, and large quantities of it can be applied without toxic effects, presumably because of its low solubility. Further work on the properties of the salts is in progress.

Cuttings.—The effectiveness of aqueous solutions of  $\beta$ -naphthoxyacetic acid in causing root formation was tested according to the method used by Hitchcock and Zimmerman (1936). Cuttings of Coleus Blumei were treated for 24 hours in an aqueous solution of naphthoxyacetic acid,—10 mg. per 100 cc.,—while controls were placed in tap water for the same length of time. In a week both lots had rooted, and a comparison showed more abundant but thinner roots on the experimental plants.

Cuttings of Taxus cuspidata treated with 10 mg., 5 mg., and 2 mg. of naphthoxyacetic acid per 100 cc. of tap water for 24 hours and controlled by cuttings similarly treated with 3-indole acetic acid, and also untreated cuttings, gave inconclusive results. In six weeks all lots had a well-developed callus and were about equally well rooted.

Discussion.—The data presented here indicate that  $\beta$ -naphthoxyacetic acid evokes physiological responses in plants similar to those of the numerous synthetic growth substances already reported. (Zimmerman and Hitchcock have reported on about fifty such substances.)

 $\beta$ -naphthoxyacetic acid is more toxic than its close relative,  $\alpha$ -naphthalene acetic acid, producing detrimental effects at a concentration as low as 1 per cent, especially in herbaceous plants. Another specific difference lies in its inducing positive curvatures, thus inhibiting growth by elongation, at concentrations which appear to be optimum for root induction.

Koefli, Thimann, and Went (1937) re-examined the properties of most of the known growth substances and brought forward the generalization that a closed ring system with double bonds and a side chain containing a carboxyl group at least one carbon atom removed from the ring were necessary constituents of a growth substance. Both a-naphthalene acetic acid and  $\beta$ -naphthoxyacetic acid fall

within these minimum requirements for a growth substance

The fundamental characteristics of growth substances are exhibited by both compounds, although they differ in specific reactions, as might be expected. It would seem that the only rational conclusion to be drawn is that proposed by Söding (1936) and accepted by Zimmerman, Hitchcock, and Wilcoxon (1936) that growth substances are nonspecific.

The reaction of naphthoxyacetic acid upon the petiole of *Mimosa* is noteworthy, since it seems to affect the permeability of the parenchyma of the pulvinus. This is inferred from the fact that the response of the leaf is modified, although there are no other apparent changes. However, a direct investigation on this point was not made, and this must therefore stand as a conjecture.

#### SUMMARY

The properties of  $\beta$ -naphthoxyacetic acid are described and its synthesis detailed. Its activity was tested by means of various concentrations in lanolin

paste applied to intact stems and leaves of Ocimum Basilicum, L., Mimosa pudica, L., Eranthemum nervosum, R. Br., and Lycopersicum esculentum. Mill. Evidence of the diffusibility and physiological activity of β-naphthoxyacetic acid was shown in all of them. Curvatures of stems and leaves resulted from unilateral treatment and in Ocimum and Lycopersicum were subsequently followed by the formation of roots over large areas of the stem. A 0.1 per cent paste proved optimum for this rooting response. In Mimosa pudica an inhibiting effect of the substance on the normal reaction of the pulvini was observed, which prevented the petiole from dropping after stimulation. Cuttings of Coleus Blumei, Benth., and Taxus cuspidata, Sieb. & Zucc., treated with an aqueous solution of the material resulted in more abundant roots in the former as the result of treatment, while the results with the latter were inconclusive.

Sodium and potassium  $\beta$ -naphthoxyacetate also were found to be active.

## STUDIES IN THE GENUS LESQUERELLA 1

### Reed C. Rollins

PAYSON IN 1922 completed a thoroughly creditable monograph of Lesquerella which is the standard reference on the genus. Since then Fernald (1933), Munz (1929, 1932), Wiggins (1933), Peck (1934), and Cory (1930) have added new species, which together with those proposed in the present paper strongly indicate that this chiefly west-American genus is not entirely known even now. During several field seasons material of Lesquerella was collected for taxonomic and cytological investigation. The results of a study of this material, together with the description of a new variety collected in Alaska by Miss Edith Scamman, form the basis for the present report. The chromosome numbers summarized in table 1 were determined from aceto-carmen smears of root-tips and developing pollen. Specimens of each collection are in the Gray Herbarium of Harvard University.

These data are not sufficient to form the basis for any general conclusions regarding the cytology of Lesquerella, but two significant points become clear. First, there is an apparent aneuploid relationship between species of Lesquerella, a condition not commonly found in the Cruciferae. According to Manton (1932), aneuploidy between species in the familv is found chiefly in the Brassicinae. Second, polyploidy occurs naturally in at least some species of the genus. It is interesting to note that the polyploid L. ludoviciana from Mesa County, Colorado, exhibits the typical "gigas" characteristics often associated with plants possessing a multiple genom. Plants of this collection are several decimeters taller; the pedicels are more remote in the inforescence; the stellae are larger and form a less dense cover on plant parts, and the siliques are slightly larger than in the usual form of the species.

Several species of Lesquerella have been grown in the greenhouse for the purpose of observing their ontogenetic development and the effect of altered environmental conditions on the disposition of the indument over the plant surface. Those familiar

<sup>1</sup> Received for publication March 29, 1939.

with section Eulesquerella of the genus are aware that the plants of most species are literally encrusted with a dense covering of nearly orbicular stellae. It is a current problem in dealing with the systematic position of many varieties and species in the Cruciferae as to how much weight can be given to the presence or absence of an indumentum. Thus, by demonstrating the stability or lack of stability of this feature, some clue as to its usefulness as a taxonomic criterion should be obtained. In L. arctica var. Scammanae, L. subumbellata, L. intermedia, L. alpina, L. ovalifolia, and L. calcicola greenhouse plants were critically examined and compared with the specimens from which seed had been obtained in each instance. Particular attention was given to the abundance and disposition of the stellae. These were found to differ in no discernible way in the same species whether they were greenhouse grown or came from their natural habitat. From this we may roughly conclude that under greenhouse conditions of reduced sunlight and increased humidity, the abundance and disposition of the indument of Lesquerella is unaltered in firstgeneration plants. In connection with these observations, it was interesting to note that the cotyledons were in every case perfectly glabrous. The first pair of true leaves were always densely encrusted with stellae as in the later foliage.

The following new entities have been discovered in Lesquerella in the past several years.

Lesquerella calcicola sp. nov. (fig. 1A, B).—Perennial, caespitose, silvery stellate-pubescent throughout; caudex simple or closely branching, elongated, often producing sterile shoots; stellae small, closely appressed, rays numerous and coherent at base; stems coarse, erect, simple, 1–3 dm. long; basal leaves numerous, petiolate, linear-oblanceolate, acute, flat, 4–10 cm. long, 4–6 mm. wide; cauline similar, 2–4 cm. long, 3–5 mm. wide; inflorescence racemose, congested; pedicels stout, spreading with a strongly sigmoid curve upward, 1–1.5 cm. long; petals yellow, spatulate, retuse, 9–11 mm. long; sepals linear-oblong, inrolled at apex, 4–6 mm. long, 2 mm. wide; siliques sessile, oblong or oval in outline, erect, com-

L. ludoviciana	Uinta Co., Wyoming	Rollins	2237	5	

pressed at apex, stellate-pubescent, 6-9 mm. long, 4-5 mm. wide; style 4-5 mm. long, stigma expanded; ovules 2-4 in each loculus; seeds orbicular, wingless, ca. 3 mm. broad; cotyledons accumbent.

Herba perennis caespitosa undique indumento argenteo-stellato tecta; caulibus erectis vel procumbentibus simplicibus; foliis radicalibus lineari-oblanceolatis acutis 4–10 cm. longis, 4–6 mm. latis; pedicellis divaricatis 1–1.5 cm. longis; floribus subluteis racemosis congestis; siliculis oblongis vel ovatis stellato-pubescentibus 6–9 mm. longis; stylo 4–5 mm. longo; loculis 2–4-ovulatis; seminibus immarginatis ca. 3 mm. latis.

Colorado: limestone or gypsum outcrop, 3 miles east of San Francisco Creek, 8 miles northwest of Trinchera, Las Animas County, July 13, 1937, Rollins 1861 (type in Gray Herb.); 10 miles south of Pueblo, Pueblo County, July, 1937, Rollins 1799 (G). New Mexico: Emery Gap to Branson, Colorado, Union County, June, 1924, Eggleston 20148 (G).

Lesquerella calcicola is nearest related to L. intermedia from which it differs in having broader, petiolate, non-involute basal leaves which are 4-10 cm. long. The basal leaves of L. intermedia are nar-

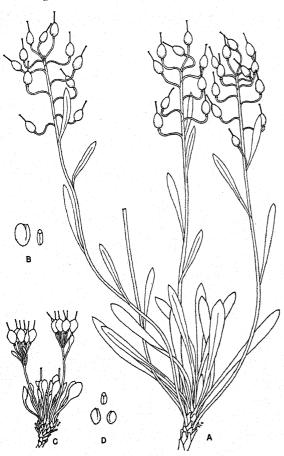

Fig. 1.—A, B. Lesquerella calcicola Rollins, drawn from Rollins 1861; A, habit sketch,  $\times \frac{1}{2}$ ; B, seed in broad view and transverse section,  $\times 2$ .—C, D. Lesquerella subumbellata Rollins, drawn from Rollins 1758; C, habit sketch,  $\times 1$ ; D, seed in broad view and transverse section,  $\times 2$ .

rowly linear, involute and only 1-4 cm. long. The pedicels of L. calcicola are definitely sigmoid, whereas those of L. intermedia are straight or nearly so. L. calcicola has pods which are oval to oblong, compressed at apex and 6-9 mm. long; in L. intermedia the silique is nearly round or slightly oval, uncompressed at apex and 4-6 mm. long. There are 2-4 ovules in each loculus of the former species and 3-8 in each loculus of the latter. L. calcicola is a taller, more robust plant with sterile soboles terminating the main axis; in L. intermedia the growing point usually produces a fertile shoot.

The types of those species of Lesquerella related to L. calcicola have been studied, with one exception. Specimens of L. valida Greene have not been available for examination directly. The original description of this species leaves little doubt that it differs widely from L. calcicola. However, in order to be doubly sure that no error was being made in describing my plants as new, specimens were transmitted to Dr. Theodor Just, who kindly compared them with the type of L. valida in Greene's herbarium at the University of Notre Dame. Dr. Just concluded that the most conspicuous differences between these species were to be found in the shape and dimensions of the foliage, but that these were by no means the only points of divergence. The basal leaves of L. valida are obovate to broadly spatulate with an obtuse apex and only 1-2.5 cm. long. Actually the two species appear not to be very close relatives.

LESQUERELLA subumbellata sp. nov. (fig. 1C, D).-Perennial, silvery stellate-pubescent throughout; stellae small, closely appressed, rays numerous, forked, irregularly coherent at base; caudex closely branched; stems erect, few to several, slender, simple, 1-3 cm. long; basal leaves numerous, linear to linear-oblanceolate, 1-2 cm. long; blade expanded, obtuse or acute, tapering abruptly to a long petiole; cauline one or two, similar to basal; pedicels spreading, nearly straight, 3-6 mm. long; inflorescence corymbose, appearing umbellate in fruit; sepals oblong, narrowed to an acute apex, 2.5-4 mm. long, 1-1.5 mm. wide; petals yellow, lingulate, retuse, 4-7 mm. long, 1.5-2.5 mm. wide; filaments slender, abruptly dilated at base; siliques sessile, obovate in outline, flattened parallel to partition, densely pubescent, 2.5-3.5 mm. long, nearly as broad, vacant apex flattened; style purplish, 1.5-2.5 mm. long, stigma unexpanded; seeds marginless, brown, orbicular to slightly oblong, ca. 2 mm. long; ovules two in each loculus, funiculi attached for one-fourth their length; cotyledons accumbent.

Herba perennis undique indumento argenteo-stellato tecta; caulibus tenuissimis erectis simplicibus 1-3 cm. longis; foliis radicalibus integris lineari-oblanceolatis 1-2 cm. longis; floribus paucis subluteis corymbose dispositis; siliculis obovatis vel subglobosis sessilibus stellato-pubescentibus 2.5-3.5 mm. longis; stylis subrubris 1.5-2.5 mm. longis; loculis 2-ovulatis; seminibus immarginatis ca. 2 mm. longis.

Utah: limy knoll-crest, juniper belt, foothills of the Uinta Mountains, 18 miles north of Vernal, Uintah County, June 17, 1937, Rollins 1758 (type in Gray Herb.); south of La Point Road, 4 miles southwest of Vernal, May, 1933, Graham 7833 (G).

This species is most closely related to L. condensata and its variety laevis but differs from both in a number of significant ways. The stellae of L. subumbellata are small, short-rayed, and closely appressed; the pedicels are straight; the siliques are obovate with obtuse apex, 2.5-3.5 mm. long, and the purplish style which is about 2 mm. long has an unexpanded stigma. In L. condensata the stellae are larger, with long, distinct rays; the pedicels tend to become sigmoid; the ovate to globose siliques have a tapering apex and are 3-5 mm. long. The style which is 2-3 mm. long has an expanded stigma. These species differ in habit of growth, L. subumbellata having slender, well-exserted stems and a much contracted delicate caudex instead of shortened stems which are virtually buried in a pulvinate cushion of leaves as in L. condensata. The latter species has a robust, muchbranched caudex which is usually subterranean. Geographically, L. condensata and var. laevis are found on the west and east side of the Continental Divide in Wyoming and Montana. L. subumbellata is apparently endemic in the Uintah Basin of Utah.

LESQUERELLA ARCTICA (Wormsk.) Watson, var. Scammanae var. nov.—Fruiting stems 1-3 dm. long, mostly erect; basal leaves spatulate, tapering to a long narrowed petiole, 1-2 cm. broad, 5-15 cm. long; fruiting pedicels 1.5-4 cm. long; silique slightly elongate, nearly glabrous, scattered stellae often present; style 2-3 mm. long.

Herba perennis; caulibus 1-3 dm. longis; foliis radicalibus 5-15 cm. longis, 1-2 cm. latis; pedicellis erectis 1.5-4 cm. longis; stylis 2-3 mm. longis.

Alaska: Rapids Lodge, 138 miles south of Fairbanks on Richardson Highway, August 7-10, 1936, Edith Scamman 216 (type in Gray Herb.); August 25-28, 1937, Edith Scamman 1000 (G).

Even when the widest natural variation in Lesquerella arctica is taken into account, the variety here proposed appears amply distinct as a subunit. Variety Scammanae has stems, leaves, and pedicels nearly twice the length of those in the species proper. The new plant is isolated from the typical species in the interior of Alaska.

The question of the proper use of the specific epithet argentea in the genus Lesquerella has recently come to my attention. In this connection, it should be pointed out that the earliest use of Lesquerella argentea was that of Watson (1888) based on Vesicaria argentea Schauer. Payson (1922) failed to recognize this combination as valid presumably because Watson placed a parenthetical question mark between the generic and specific name when the original combination was made. This, it seems to me, must be interpreted as biological doubt rather than nomenclatorial hesitancy; therefore, the name cannot be rejected on that account. With L. argentea (Schauer) Watson, accepted as a valid name, then L. argentea (Pursh) MacMillan (1892) based on Myagrum argenteum Pursh (1814), must be rejected in favor of L. ludoviciana (Nuttall) Watson (op. cit.), which is based on Alyssum ludovicianum Nuttall (1818). Payson (op. cit.) assumed L. ludoviciana to be rare west of the Continental Divide, but I have seen plants of this species growing in abundance in western Wyoming, western Colorado, and eastern Utah. Graham (1937) has reported it to be a frequent plant of low and mid-altitude dry places in the Uintah Basin of Utah.

#### SUMMARY

Chromosome numbers are presented for six species and one variety of Lesquerella, based on the examination of eleven samples of material collected from naturally occurring plants. From these data it is concluded that aneuploidy exists between certain species and that natural polyploidy is present in at least one species of the genus. The indument on plants of five species and one variety of Lesquerella grown in the greenhouse was found to be similarly disposed and equally abundant as on plants of the same entities obtained from their natural habitats. Two new species and one new variety are proposed in the genus Lesquerella.

## PRODUCTION OF GROWTH SUBSTANCE BY BACTERIA IN MEDIA CONTAINING SPECIFIC ORGANIC AND INORGANIC NITROGENOUS COMPOUNDS <sup>1</sup>

Paul R. Burkholder

The formation of growth-promoting substance (auxin) by microorganisms has been observed in recent years by a number of investigators, but comparatively little knowledge exists concerning the relationship between definite compounds present in the substrate and elaboration of these special substances. In this study pure cultures of Aerobacter aerogenes and Escherichia coli were grown in synthetic media containing single amino acids<sup>2</sup> or inorganic salts as the only source of nitrogen. After periods of incubation, the cultures were tested for growth substance according to a standard Avena coleoptile curvature method commonly used for detection of phytohormones causing cell enlargement.

METHODS.—The culture medium employed for growing the bacteria was glycerol agar made up according to the formula used by Koser and Rettger (1919). Its constitution is as follows: NaCl, 5.0 g.; MgSO<sub>4</sub>, 0.2 g.; CaCl<sub>2</sub>, 0.1 g.; KH<sub>2</sub>PO<sub>4</sub>, 1.0 g.; K<sub>2</sub>HPO<sub>4</sub>, 1.0 g.; glycerol, 30.0 g.; distilled water, 1,000 g.

Sufficient agar was added to make a 2 per cent mixture. Nitrogen was supplied to the cultures by adding a single amino acid to the substrate at the rate of 1 gram per 1,000 cc. of medium. In experiments with inorganic sources of nitrogen the composition of the medium was similar, but 1 gram of NH<sub>4</sub>Cl or of KNO<sub>3</sub> was used per liter, and 4.0 grams of NaCl were added instead of 5.0 grams per liter. All media were put into pyrex culture tubes and sterilized in an autoclave. Only 2 cc. of medium were used in each tube, and the agar was allowed to solidify in an extremely slanted position, so as to permit considerable aeration of the culture during the period of growth. The tubes were inoculated from ordinary nutrient agar slant cultures of A. aerogenes and E. coli, using a small amount of inoculum.

The inoculated tubes were kept in a moist incubator at 33.0°C. for about two or four weeks. Sterile tubes of media were held as controls along with the cultures. During the period of incubation, some of the cultures developed pronounced colors and heavy growths of bacteria, while others remained less colored or showed less growth. At the time selected for making tests for growth substance, agar slants containing the bacteria as well as sterile control tubes of the same media were melted in a water bath, and from each sample agar plates were cast in a brass mold. Great care was exercised in keeping all preparations clean and free from contamination during the testing procedure. The standard size

 Received for publication April 8, 1939.
 These amino acids were supplied by the Dow Chemical Company to the Department of Botany, Connecticut College, where part of the experimental work was performed. agar plate was cut into twelve pieces and then tested on one dozen Avena coleoptiles according to methods published elsewhere (Avery, Burkholder, and Creighton, 1937).

In certain instances—e.g., with tryptophane—unexpected curvatures were found, and further dilutions of the preparation (originally 1 part of amino acid in 1,000 of medium) were made at the time of testing with pure aqueous agar to yield theoretically one part of the original amino acid in 10,000, 100,000, and 1,000,000 of prepared agar. Preliminary work indicated that with the other amino acids tests could be made satisfactorily without dilution, using the agar as it was made up in the cultures.

RESULTS WITH TRYPTOPHANE.—The results with tryptophane were somewhat different from those obtained with other compounds. A brilliant red color was formed in the medium supporting a rich growth of *E. coli*, while in the cultures of *A. aerogenes* the color was very dark brown at the end of the growth period. Cultures of both organisms in agar supplied with 1 part of tryptophane in 1,000

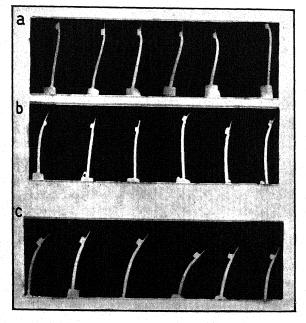

Fig. 1. Curvatures of Avena coleoptiles treated with agar blocks from cultures of A. aerogenes: a, curvatures toward the blocks indicating growth inhibition with an undiluted (1/1,000) tryptophane culture; b, curvatures away from the blocks indicating growth promotion with a diluted (1/100,000) tryptophane agar culture; c, curvatures indicating the presence of growth promoting substance formed in NH<sub>4</sub>Cl agar cultures.

parts of medium produced Avena curvatures toward the applied agar blocks (fig. 1a). This response indicates that growth of the oat tissues in the region immediately below the source of growth substance supply was less than in the opposite side of the coleoptile. Further dilution of the cultures with pure agar vielded test curvatures which were away from the blocks, indicating greater growth in the side under treatment (fig. 1b). The accompanying table 1 gives the values of the curvatures resulting from tests on several different concentrations of substrate made up by diluting the media at the conclusion of the growth period as indicated. It should be noted that in older (30 days) cultures of A. aerogenes the extent of growth inhibition at higher concentrations was somewhat greater than that found in young (14 days) cultures.

Tryptophane agar which had not been autoclaved gave no curvature when tested fresh. Appreciable curves could be obtained with the sterile medium which had been autoclaved and allowed to stand in the incubator for 2 weeks. Sterile autoclaved tryptophane agar originally containing 1/1,000 of the amino acid yielded upon two separate occasions growth promoting curvatures which averaged 4.5° and 4.0°. It may be concluded that heat treatment converts this amino acid to some extent into an active compound. The activity subsequent to autoclaving was never found to be as great as that produced by the action of bacteria growing on the media

Other investigations on tryptophane activation gave some additional information. A pH series of solutions of tryptophane 1/1,000 in water was set up by adding appropriate amounts of HCl or KOH to give the following pH values: 2.0, 3.0, 4.4, 6.9 (tryptophane only in water), and 9.4. After standing at 33°C. for 14 hours, these solutions were mixed individually with equal parts of 3 per cent agar and tested on Avena coleoptiles in a standard manner. No curvatures were found in the test plants after two hours. Apparently the activation of tryptophane in solution is not primarily dependent upon hydrogen-ion concentration, and acidification of the medium in the course of metabolic action of the bacteria would not account for the results obtained.

Further work indicates that temporary activation of tryptophane in aqueous solution takes place, but

the growth promoting property is gradually lost with time. Using a straight growth test method with Avena coleoptiles, as has been employed by Scheer (1937), Miss Genevieve Sargent was able to demonstrate with 1/1,000 tryptophane a spontaneous, but temporary, activation at room temperature.

With the Avena curvature method it was possible to demonstrate complete inactivity of freshly made aqueous solutions of tryptophane. However, after this solution had stood for about four hours at 80°F., curvatures of 3.6 degrees were obtained during the test period of two hours immediately following. Upon further standing in a test tube for 16 or 19 hours, this growth promoting property of the tryptophane solution was lost. Since the activity of tryptophane cultures of bacteria which stood for several weeks was higher than that of sterile control media, it may be concluded that the microorganisms exerted some kind of activating influence which resulted in the formation of a comparatively stable growth substance.

The question arose as to whether or not bacterial cells or the aqueous filtrate from bacteria would be active or capable of activating tryptophane and other amino acids within a short period of time. Tests were made by the Avena curvature technique using agar impregnated with a heavy suspension of A. aerogenes and E. coli, which had been grown on peptone agar, washed with a small amount of distilled water, and finally filtered with a Mandler filter. No curvatures were obtained with agar containing these suspended organisms, nor with the filtered water extract made up in agar. A portion of the aqueous extract was allowed to stand for 7 hours in the presence of an equal volume of 1/1,000 tryptophane. Tests made on this mixture as well as on the amino acid alone in agar gave no indication of growth substance activity. Furthermore, the bacterial extract standing for 7 hours in the presence of proline, cystine, and aspartic acid vielded no curvatures when tests were made on the mixture.

RESULTS WITH OTHER AMINO ACIDS.—Averages of the growth curvatures resulting with 16 different nitrogenous compounds which had supported growth of the two species of bacteria are presented in table 2. The sterile media showed no growth promoting activity when stored in tubes for the same periods of time as the inoculated media. Some of the com-

l-tyrosine		8.6	0	13	15	
l-valine		2.6	0	14	13	

pounds—e.g., l-valine—were but slightly activated by either of the two organisms. The majority of the substrata showed considerable activation by both organisms, but some yielded greater activity with one organism than with the other. In the case of methionine, E. coli gave high activity, while A. aerogenes was apparently inactive, a result possibly associated with poor growth of the latter in this medium.

For the purpose of finding the effect of concentration of the activated materials upon the curvatures obtained in the tests, series of dilutions of seven amino acid media were made at the time of testing. Results of these observations are given in table 3.

In contrast with the results obtained with tryptophane, dilution of these seven amino acid substrata gave curvatures indicating growth promotion, varying in degree directly with concentration of the media. Maximum responses were found with the highest concentration of 1/1,000 and less with dilu-

tion to 1/10,000; with further dilution to 1/100,000 or beyond, all detectable activity disappeared. These data, presented in table 3, represent the results on separate cultures from those reported in table 2, thus serving to substantiate the findings.

INORGANIC NITROGEN.—During the course of these experiments the question arose as to whether bacteria are able to produce growth promoting substance from materials present in media containing simple compounds of nitrogen. Cultures of A. aerogenes obtained from Dr. N. R. Ziegler, University of Missouri, were grown on basal glycerol agar in which ammonium chloride or potassium nitrate formed the sole source of nitrogen. Inoculated cultures and sterile media were allowed to incubate at 33°C. for one week, and then tests for growth substance were made directly on the agar in the usual way with Avena coleoptiles.

In these tests the sterile substrata gave no curvatures. A. aerogenes cultures on NH<sub>4</sub>Cl yielded curvatures averaging 17.6 degrees (see fig. 1c).

Table 3. Avena curvatures (in degrees) obtained with A. aerogenes cultured in several different amino acid media tested at four different dilutions.

	Dilution	Age of				
Amino acid in medium	1/1,000	1/10,000	1/100,000	1/1,000,000	culture	
	Degrees	Degrees	Degrees	Degrees	Days

glycine	6.5	2.0	0	0	28	
d-arginine	13.3	8.3	0	0	28	
l-alanine	10.5	4.3	0	0	28	

Cultures on KNO3 gave 11.3 degrees of curvature. This same organism produced appreciable amounts of growth substance, also, when cultured on the basal medium containing asparagin as the sole source of nitrogen.

It seemed desirable to test for possible transfer of any appreciable amount of growth substance in making inoculations on the culture media containing inorganic nitrogen. Accordingly, A. aerogenes was allowed to form a luxuriant growth upon peptone nutrient agar slants. A large quantity of bacterial growth (many times the amount used as inoculum in making ordinary transfers) was mixed with pure aqueous 2 per cent agar, and tests were made in the usual way with Avena coleoptiles. The test plants behaved just as when treated with plain agar blocks, and it may be concluded, therefore, that in making the inoculations no detectable amount of growth substance was transferred from the cultures on peptone.

Discussion.—Formation of certain growth-promoting substances by microorganisms and their chemical nature has been studied by a number of investigators. Brief reference to some of the outstanding facts will be made here. More than 50 years ago, E. and H. Salkowski (1880, 1885a, 1885b) observed the formation of indole acetic acid and related compounds during the decomposition of protein by mixed cultures of bacteria. Hopkins and Cole (1903) reported on the appearance of indole acetic acid in cultures of Escherichia coli grown in the presence of tryptophane. Herter (1908) pointed out that indole acetic acid, derived from bacterial activity on the intestinal contents, may be excreted in urine, and the following year (Herter and Ten Brock, 1909) published an account of the formation of this substance in cultures of Proteus vulgaris grown on peptone and beef extract. Frieber (1921) described the formation of indole acetic acid from tryptophane in cultures of indole forming bacteria, when sugar is present as a preferred source of carbon; in the absence of sugar, it appears that tryptophane may be converted to indole. Apparently, indole-negative bacteria may form indole acetic acid from tryptophane, whether or not sugar is available. Discussion of other work on the subject may be found in the textbook by Gilman (1938).

New impetus was given to the search for growth regulating substances in plants when the properties of auxins were discovered and quantitative methods for their detection were worked out. Nielsen (1930) found in Rhizopus cultures a new growth regulating substances which he named rhizopin. Then Kögl and Kostermans (1934) succeeded in isolating the highly active indole acetic acid from yeast. Thimann (1935) carried through a number of purification stages the active substance from cultures of Rhizopus suinus; it was shown that formation of indole acetic acid by this fungus grown upon peptone was governed by the amount of tryptophane present and the extent of aeration. The probable production of indole acetic acid by oxidative deamination of tryptophane has been pointed out clearly by Went and Thimann (1937). Boysen Jensen (1932) showed that Aspergillus niger produces active substances from histidine, lysine, leucine, tyrosine, phenylalanine, and tryptophone, but not from glycine, alanine, asparagine, cystine, proline, or arginine. This same author (Boysen Jensen, 1931a) observed the production of a substance active on Avena in cultures of a number of species of bacteria grown on peptone media. Brown and Gardner (1936) obtained evidence for the formation of growth substance by B. tumefaciens.

Thimann (1936) found that root nodules containing R. leguminosarum are centers of growth substance formation. Production of growth substance by clover nodule bacteria grown in yeast water medium plus 0.02 per cent tryptophane has been reported by Chen (1938); no growth substance was found in a culture of nitrogen fixing bacteria grown in the medium without tryptophane. Still more recently Georgi and Beguin (1939) have reported on the elaboration of growth substance by four species of Rhizobium and B. radiobacter cultured on a synthetic medium containing mannitol, mineral salts, and 0.05 per cent tryptophane. All these bacteria were able to produce special substances, in media containing tryptophane, which gave curvature in the Avena test. With mannitol as the source of carbon and KNO3 as the sole source of nitrogen (tryptophane not added), no active substances were produced in the medium.

Few of the earlier workers held any notion whatsoever concerning the possible rôle of bacterial products in regulating the growth of higher plants. Bottomley (1920) and others observed that nitrogen fixing bacteria are able to elaborate substances from carbohydrate and elementary nitrogen which promote the growth of Lemna plants. More recently, it has been found that small amounts of barnyard manure enhance growth of crop plants in some other way than can be explained merely by the content of nutrient elements and gross organic matter (Hartley and Greenwood, 1933). In view of the evidence now available, it seems probable that auxins, as well as vitamins (see Williams and Spies, 1938), produced by microorganisms in nature may have considerable influence upon growth

Up to the time when the present experiments were undertaken, it had not been shown whether or not bacteria are able to form growth substances (active on Avena) when cultured on various single amino acids or on inorganic nitrogen. The experiments reported herewith show that sterile media containing single amino acids, KNO3, or NH4Cl remain inactive (with the single exception of tryptophane) when tested on Avena after a period of 1 to 4 weeks. Tryptophane was unique in that autoclaved sterile preparations were somewhat active. (Other workers have found that the conversion of tryptophane by heat can be avoided in preparing sterile media by the use of fine filters (Georgi and

of higher plants.

Beguin, 1939), a fact which should be of practical use in future work). The data indicate further that A. aerogenes and E. coli grown in glycerol agar with single amino acids as the only source of nitrogen, and A. aerogenes grown on media supplied with inorganic nitrogen produce growth substance active on Avena. Even in the autoclaved tryptophane medium there was further elaboration of active substance by the bacteria. The presence of glycerol undoubtedly plays an important part in the synthetic processes of these organisms, though the precise relationship of an extra carbon source in the metabolism of amino acids and synthesis of growth substance is not known. In reviewing the literature, one finds considerable emphasis placed upon conversion of tryptophane to growth substance (sometimes called heteroauxin). The results reported here indicate clearly that at least some bacteria are able to form growth substance on media having no added tryptophane.

The medium containing 1/1,000 of tryptophane, in which bacteria had grown, brought about growth curvatures toward the site of application of agar on the Avena coleoptiles, while dilutions of this culture (e.g., 1/100,000) elicited curvatures away from the agar blocks. In seeking to explain the remarkably strong action of tryptophane cultures, involving both negative and positive curvatures, it should be remembered that by oxidative deamination this amino acid can be readily converted to indole fatty acids which are powerful growth substances (see Went and Thimann, 1937; Gilman, 1938). The cross transfer and growth stimulation of unilaterally applied synthetic substances in the Avena test technique have been described earlier (du Buy and Nuernbergk, 1930; Avery, Burkholder, and Creighton, 1937), and it would seem that some such explanation may be applicable here. It is known that large doses of this class of substances may cause inhibition of growth in coleoptiles (Bonner, 1933) and in buds (Thimann, 1937). Even a small amount of externally applied auxin inhibits growth in roots, but a still smaller quantity (0.2 gamma per liter) may stimulate growth in at least some roots (see Thimann and Bonner, 1938). It is possible to take the position that curvatures toward the blocks were brought about by inhibiting action of the substance at high concentrations under the blocks, and that by lateral transport small but sufficient quantities were moved into the opposite side to actually stimulate growth there. These positive curvatures were of course much greater than those which are known to occur with pure agar blocks unilaterally applied, where regenerated auxin reaches a higher concentration on the opposite side from the block and promotes a positive curvature of about 2.5 degrees (see Went and Thimann, 1937). The report of Stewart, Bergren, and Redeman (1939) concerning the occurrence of a growth inhibitor in radish cotyledons, which when applied to Avena causes positive curvatures, is of considerable interest in this connection. The work

of Goodwin (1939) also indicates that inhibiting substances may have an appreciable influence on Avena curvature. It still remains to be demonstrated whether bacteria cultured on tryptophane actually produce special inhibiting substances. Tests with the straight growth technique might throw more light on this question.

The extent to which amino acid may have been activated by the bacteria is worth consideration, on the assumption that some sort of direct conversion actually occurred. The maximum activity found with the various media amounted to about 14 to 16 degrees curvature. Curvatures of approximately this amount have been observed under the same test conditions with agar blocks containing synthetic indole acetic acid at a concentration of 156 gamma per liter. If it is assumed that the activity and molecular weight of the substances produced in bacterial cultures is of the same order as that of this well-known substance, then it might follow that about 156 gamma of activated substance per liter were present in the bacterial agar when tested. The amount found at the time of testing may not represent the total converted during the growth period, and it is indeed probable that considerable quantities of active material formed during the growth period are rendered inactive upon prolonged standing with the complicated mixture of substances in the medium. Keeping in mind the obvious limitations upon the correctness of our assumptions, it might still be possible to make a theoretical comparison of the number of molecules of active substance found in relation to the quantity of amino acid supplied in the substrate. Calculations on this question lead to the conclusion that in these particular cultures only small fractions of the supplied amino acids were converted into growth promoting substance. It is not known what the quantitative yield of growth substance may be in relation to the supply of amino acids; such calculations might be made from results of experiments with media containing much smaller quantities of amino acids than those employed in this work.

Theoretical discussion is actually of little value at this point; much additional work is needed to give anything like a satisfying explanation of the problem. Further investigation might even disclose the elaboration of non-nitrogenous growth substances of the nature of auxin a or b (see Boysen-Jensen, 1936), derived from carbohydrate (or glycerol) metabolism. Since conversion of tryptophane to active compounds, such as indole acetic acid and indole propionic acid (see Gilman, 1938), is well known, it seems natural to attribute formation of growth substances in the cultures containing this amino acid to bacterial action upon it.

In the absence of contrary evidence, it might be assumed that the various other amino acids are in some way converted to active substances. Supporting this view are the findings of Boysen-Jensen (1931b) that Aspergillus failed to produce growth substance on media containing nitrate or ammonia

as a source of nitrogen even though growth did take place. In view of the wide variation in structure of the nitrogenous compounds employed in this work, it seems reasonable to postulate formation by the bacteria of more than one kind of growth regulator, perhaps substances altogether different from the active indole fatty acids. Certainly the observation that growth substance is produced in ammonium or nitrate agar would indicate something of the remarkable synthetic powers of these microorganisms. It may be pointed out here that green plants also synthesize auxins out of organic materials made originally from inorganic compounds.

The very extensive chemical powers of microorganisms have oftentimes suggested questions concerning the possible benefits which may be derived from the end products of their own metabolism. Are growth substances, such as the auxins, of any value to bacteria and fungi? In recent years this question the negative (see Boysen-Jensen, 1936; Went and concerning auxins usually has been answered in Thimann, 1937), if answered at all.

A current paper by Ball (1938), however, indicates that 3-indole acetic acid added in amounts of 1 to 10 parts in 10<sup>7</sup> parts of synthetic medium more than doubled the rate of growth of Escherichia coli in liquid cultures. Since tryptophane was present in the culture medium used by Ball, one might inquire how the addition of small amounts of 3-indole acetic acid would be beneficial. It was concluded that "heteroauxin . . . stimulates the cells to further growth and division which produces more cells and more heteroauxin." There may be some sort of analogy here akin to the findings of West and Wilson (1939) that growth of Rhizobium trifolii cultures is remarkably stimulated in the first few hours by small additions of thiamin and flavin; then during subsequent growth, the bacteria produce ample supplies of these vitamins for their use.

It seems clear both from earlier work and in the light of the present report that microorganisms in nature are continually converting organic substrate, in some small part at least, to special substances capable of exerting regulatory action in the growth of higher plants. Certain members of this general class of growth substances, under appropriate circumstances, are known to be capable of penetrating the roots of green plants grown in soil (Hitchcock and Zimmerman, 1935; Loehwing and Bauguess, 1936; Greenfield, 1937). It has been found that these substances, which enter and move about in

plants, stimulate growth of the plant body and evoke many other remarkable responses. It seems reasonable, therefore, to suppose that traces of growth substances produced in agricultural soils or in the decomposition of farm manures used as fertilizers may exert considerable influence on the growth of field and garden crops. Extension of this line of thought would lead into problems concerning the activity of microorganisms in many different directions-e.g., in the usefulness of organic fertilizers; the action of mycorrhiza and nodule bacteria, effects of the crown gall organism and other parasites causing pathological hypertrophy, etc. Speculation is of little real value, however, without facts. It may be said that concerning the formation of growth substances by microorganisms there exists already sufficient knowledge to indicate fruitful rewards from further investigations into the mechanism of their elaboration and their rôle in the growth and development of plants.

#### SUMMARY

Avena coleoptile tests for growth promoting substances were made on cultures of Aerobacter aerogenes and Escherichia coli grown on glycerol-mineral salts-agar in which the sole source of nitrogen was either an amino acid, KNO<sub>3</sub>, or NH<sub>4</sub>Cl.

Substances producing coleoptile growth curvatures were found in the cultures supplied with any one of 17 different amino acids. Furthermore, A. aerogenes formed active substance in synthetic media containing either KNO<sub>3</sub> or NH<sub>4</sub>Cl. Uninoculated media remained inactive, with the exception of tryptophane agar which showed some activity following sterilization in the autoclave.

Although growth promotion was observed with all the inoculated substrata in certain ranges of concentration, bacterial cultures supplied with tryptophane gave positive *Avena* curvatures (toward the blocks) at higher concentrations of the activated medium, indicating growth inhibition.

Since it has been shown that bacteria elaborate growth substances in media containing any one of widely different nitrogenous compounds, it is probable that different substances having the physiological properties of auxins may be synthesized by microorganisms in ways other than by the well-known conversion of tryptophane.

# REGENERATION OF ROOTS FROM TRANSPLANTED COTYLEDONS OF ALFALFA, MEDICAGO SATIVA<sup>1</sup>

Orville T. Wilson

THE WRITER has called attention to the readiness with which cuttings of alfalfa regenerate roots (Wilson, 1915). La Rue (1933) listed forty-two

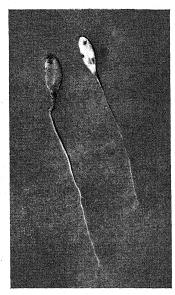

Fig. 1. Rooted cotyledons of alfalfa, Medicago sativa L. ×1.25. Photograph by Arthur Blickle.

species of plants of which he tested the regeneration of roots from cotyledons by transferring the removed cotyledons to moist filter paper in Petri dishes and noting development. Of the forty-two

<sup>1</sup> Received for publication April 24, 1939.

species, *Medicago sativa L*. was the only one which failed to regenerate roots. As this result was contradictory to the writer's experience with alfalfa, additional experiments were carried out to test the regenerating capacity of the cotyledons.

In these experiments the cotyledons were removed from seedlings in the early juvenile leaf stage and set, cut end down, in moist greenhouse soil, with most of the blade exposed. A glass cover was placed over them to prevent excessive evaporation, but this was removed after the first week. After three weeks, approximately 50 per cent of the cotyledons were green and healthy (80 per cent in one experiment). When these were removed from the soil, they were found to be well rooted in a majority of cases. In one experiment sixty-seven cotyledons out of one hundred transplanted, regenerated roots. Two rooted cotyledons are shown in figure 1.

For an adequate discussion of the problem of root regeneration from cotyledons the reader is referred to La Rue's paper (1933). The present record serves only to supplement the long list of positive results there presented.

# THE FLORAL ANATOMY OF THE AVOCADO 1

Philip C. Reece

This study of the anatomy of avocado flowers is a part of an investigation now under way on the family Lauraceae. This article is to be followed by a report on fruit bud formation of avocados and by a morphological interpretation of the apparent evolutionary tendencies in the Lauraceae, based upon comparative data.

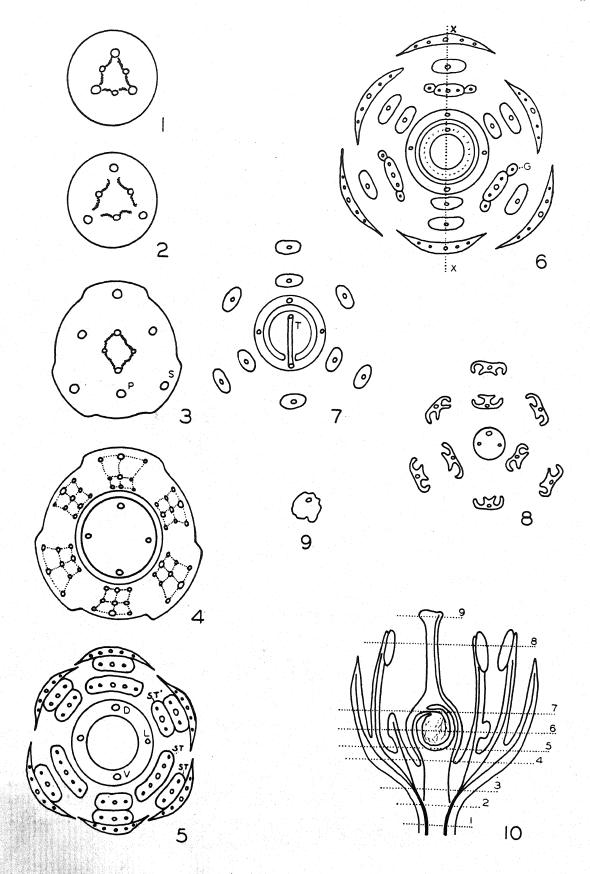

The family inhabits the tropical regions of the Americas, Asia, Australia, and Polynesia. The avocado is native to Central America and Mexico. Its culture has now become a thriving industry in the relatively frost-free areas of California and Florida.

<sup>1</sup> Received for publication April 26, 1939.

The writer wishes to express his appreciation to Dr. A. J. Eames, who, by his advice and criticism, aided in the development of this manuscript. Part of the research here reported was carried on in the laboratory of the Department of Botany, Cornell University, Ithaca, New York.

All the cultivated varieties of avocados belong to the single species, *Persea americana* Mill. (*Persea gratissima* Gaertn.)

The regular, bisexual, trimerous flowers of Persea are borne in cymose panicles. The floral plan of three, so conspicuous in this species, is popularly associated with monocotyledonous angiosperms. However, this fundamental plan of three is more prevalent among dicotyledons than is generally realized. The yellow or greenish six-parted perianth consists of two whorls upon which are inserted four stamen whorls of three members each. The anthers of the two outer whorls are introrse. Those of the third whorl are extrorse and bear glands on each side of the filament near the point of attachment on the perianth. The fourth whorl has been reduced to gland-like staminodes. The uni-

locular ovary is superior. The simple style is terminated by a small obtuse stigma. The solitary, pendulous, anatropous ovule ripens to produce a very large seed which is devoid of endosperm. The seed coat is membranous.

Examination of sections of the pedicel reveals the vascular tissue arranged in a siphonostele. Six areas of primary xylem stand out sharply, with the tissue in the intervening regions in a procambial state (fig. 1). At higher levels, approaching the receptacle, these areas depart from the stele and pass through the cortex as six tepal traces. (The term tepal is used in this report to designate any perianth segment, regardless of whether it is a member of the inner or outer whorl. At this point, no attempt is made to identify the segments as sepals or petals.) Three traces advance slightly ahead of the others and supply the outer perianth whorl (fig. 2).

After the departure of the tepal traces, the gaps left in the stele quickly close. Only a limited amount of vascular tissue remains. The stele "shrinks" toward the center of the axis, as the end of the receptacle is approached (fig. 3). The carpellary traces depart near the tip of the axis as the stele "closes in." The carpellary supply consists of a dorsal trace (midrib), two or more lateral traces, and two ventral traces (marginal veins) which are united into a single, morphologically compound vascular bundle. These traces enter the ovary (fig. 4) with the dorsal trace lying along the radius of a member of the outer perianth whorl. The ventral trace stands directly opposite the dorsal or at an angle of 180°.

The members of each perianth whorl are coherent at the base, as well as adnate to each adjacent whorl. A cup is thus formed around the base of the ovary by the perianth with the stamens perigynously inserted upon it. In this cup, the tepal traces divide, indicating that at lower levels the bundles are morphologically compound. The branching of the bundles is in a tangential plane, so that a tepal trace and two stamen traces lie upon the same radius. This is immediately followed by branching in the radial plane. Traces apparently form a reticulate vein system with anastomosing connections between the vascular supplies of the various whorls (fig. 4).

All the stamens have three traces traversing the major portion of the filament. The lateral veins in each filament weaken and disappear below the anthers. Each stamen of the third whorl possesses a gland on each side of the filament near the base. The glands are supplied by two additional veins which arise by the radial forking of the outer veins in the filament base. Then five traces are in a row (fig. 5). The veins enter the glands above the level at which the members of all the whorls become free (fig. 6).

The single, large anatropous ovule is attached to the parietal placenta near the top of the loculus. A bundle, which has been formed by the fused ventrals, enters the funiculus of the ovule and continues down the opposite side through the raphe (fig. 7). The bundle in the ovule branches profusely, so that the integument is traversed by a network of veins. These are conspicuously developed in the seed coat when the fruit is mature.

The fourth androecium whorl consists of three staminodes, which are not as high as the ovary. The anthers of the stamens of the two outer whorls are introrse, those of the third whorl are extrorse, and are borne on long filaments which extend to about twice the height of the ovary. The dorsal and two lateral carpellary traces extend up through the simple style (fig. 8). The lateral traces disappear below the stigma. The strong dorsal trace extends into the stigma (fig. 9).

It is becoming generally recognized that imperfect or incomplete flowers have attained that condition through simplification and loss of parts. They are simple through reduction and not primitively simple. Anatomical evidence of such simplification persists long after external evidence has disappeared. Therefore anatomical investigation of the floral anatomy supplies valuable criteria for a morphological interpretation of the flower.

Considerable difference of opinion exists regarding the nature of the perianth in this genus. Small (1913) believes that the perianth consists of six deciduous sepals, in two series, united at the base. Popenoe (1914) refers to the perianth as a "calyx deeply six-parted,—the corolla wanting." Gray

Fig. 1-10. Persea americana Mill. In these figures: S, sepal (outer tepal) midrib; P, petal (inner tepal) midrib; ST, stamen bundle; ST', staminode bundle; G, gland; D, dorsal carpellary trace; V, ventral carpellary trace; L, fateral carpellary trace; T, ovule trace.—Fig. 1-9. Cross section diagrams of the flower.—Fig. 1. Through the pedicel.— Fig. 2, 3. Successive levels showing the departure of the outer tepal (sepal) traces and the inner tepal (petal) traces. The carpel dorsal (midrib), the fused ventrals (marginal veins) and two median lateral veins are distinguishable at the level of fig. 3. The vascular tissue of the stele is fading out at the end of the axis.—Fig. 4. The perianth cup surrounds the base of the ovary. The sepal and petal traces have divided tangentially to produce the traces of four stamen whorls and radially to produce branch traces in each whorl.—Fig. 5. The perianth segments and the filaments of the third stamen whorl have become free. The locule is visible in the ovary.—Fig. 6. All floral whorls are free. The longitudinal section in fig. 10 is in the plane X-X. The ovule trace, derived from the fused ventrals, enters the funiculus and passes down the opposite side of the ovule near the dorsal. The integument is invested with numerous small branches of this trace.—Fig. 7. Section through the top of the ovule showing the origin of the ovule trace. The lateral stamen traces have disappeared in the upper portion of the filaments. The fourth stamen whorl reduced to staminoides has disappeared between sections indicated by fig. 6 and 7. The perianth has been omitted from this diagram.—Fig. 8. Through the anthers and style.—Fig. 9. The dorsal trace continues to the stigma-Fig. 10. Longitudinal diagram of the flower. The levels of the cross section diagrams fig. 1 to 9 are indicated. The longitudinal diagram is in the plane X-X in the cross section fig. 6.

(1908) and Hutchinson (1926) also speak of the six-parted calvx and imply the lack of a corolla. This viewpoint may be attributed to a lack of anatomical evidence and to hesitancy in interpreting the perianth of a dicotyledon as consisting of a three-parted calvx and a three-parted corolla. However, Van Tieghem (1891) considered the floral formula to be "(3 S + 3 P + 3 E + 3 E" + 3 E" + 3 E") + C" and said that "the calvx and the corolla, composed each of a single whorl, are sepaloid or petaloid, but like each other and concrescent in a tube. The median sepal is posterior."

The floral anatomy supports the view of Van Tieghem. There is no evidence that the corolla is absent. The concrescence of the perianth into a tube and the resemblance of one whorl to the other may not be accepted as valid criteria for considering that the perianth consists of a calyx only. If such reasons were to be considered valid, they should be applied in the interpretation of the perianth in liliaceous forms, in which the morphological conditions of the calyx and corolla are exactly the equivalent of those found in the perianth of the avocado. However, the fact that the perianth traces arise at two levels is in itself sufficient evidence that the perianth does not consist of a calyx alone.

Comparative studies of present plant forms as well as paleobotanical studies indicate that the fundamental type of architecture in pteropsid vascular plants is dichotomy. Working upon this theory, Hunt (1937) investigated the vascular anatomy of the style and stigma in certain groups. A study of the gross and anatomical structure of these organs convinced him that evidence still exists in the modern flower indicating that the carpel has been ultimately derived by reduction from a dichotomous branch system through the intermediate stage of an unspecialized palmately three-lobed appendage. The simple stamen commonly found in angiosperms may also have been similarly derived by reduction from a sporophyll which, in the ancestors of the angiosperms, was probably a fertile branch system.

The condition in which the vascular supply to a number of stamens arises as the result of the division of a single bundle has been investigated in a number of forms by Wilson (1937), who believes that such stamens have been derived from a primitive branch system, the ultimate branchlets of which were terminated by sporangia.

Reduction in most angiosperms has progressed so far in the stamen that only a single trace passes through the filament to the anther which consists of two bi-sporangiate synangia brought into close conjunction. It may therefore be assumed that the additional traces in an avocado stamen probably indicate a retention of a primitive condition. The various whorls exhibit various degrees of reduction. Members of the third whorl are the most primitive. Although each trace is fused with a tepal trace through part of its course, the trace later branches to produce three bundles, a median which extends to the anther and two laterals which pass some dis-

tance through the parenchyma of the somewhat fleshy stamen. The lateral bundles branch dichotomously near the base of the filament to supply the glands. Reduction of a primitive fertile branch system has probably proceeded in many directions to produce the stamen. The avocado stamen may have been derived from a much branched structure through some intermediate three-branched stage, forming a series similar to the series postulated by Hunt for the carpel.

The gynoecium consists of a single carpel. The existing carpel usually lies in the plane of a sepal (outer tepal) and is alternate with the members of the fourth androecium whorl (staminodes). However, the carpel frequently lies on the radius of a petal (inner tepal) and opposite a staminode. The writer believes that this is evidence of reduction from a multi-carpellate ancestor.

The great increase in size which comes with the ripening of the ovary is accompanied by the formation of many additional cells in the pericarp. In the mature fruit, although the main vascular system remains fundamentally the same, it is complicated by branches which are differentiated in the new tissue. These branches consist chiefly of protoxylem cells accompanied by a few elongated parenchyma cells.

The presence of a single seed with its very large embryo and no endosperm indicates a high degree of specialization. Indeed, the gynoecium has become so specialized that in so far as this species is concerned all evidence indicating the presence of more than one ovule in ancestral forms is lost. The profuse vascular supply in the integument may be regarded as the retention of a primitive characteristic. This condition has been retained coincident with the development of the large seed.

Hutchinson (1926) states that the members of the Lauraceae represent the extreme limits of reduction in the Magnolian alliance and that valvular dehiscence in this group and in the Berberidaceae is probably due to parallel evolution and is not a sign of affinity. He places them in the Apetalae but upon a different line from that giving rise to the Amentiferae.

The writer has investigated the floral anatomy of the Fagaceae (1938) and finds striking similarities of floral and inflorescence characters. Both groups are mainly tropical and display a trimerous floral plan with a six-parted perianth and twelve perigynously inserted stamens. The gynoecium in each case has apparently been reduced from a six-carpellate ancestor. A network of veins in the membranous seed coat surrounds the large fleshy embryo. The ament of the Fagaceae is also fundamentally a cymose panicle but is much more specialized than that of the Lauraceae.

The possibility of a common origin of the Lauraceae and Fagaceae in the early differentiation of Angiosperms is suggested by these similarities of floral and inflorescence characters. However, these similarities are the result of parallel evolution and do not indicate close relationship.

#### SUMMARY

This study of the floral anatomy of *Persea americana* reveals that this species is clearly a specialized form derived from a primitive angiosperm stock and that the perianth consists of a three-parted calyx and a three-parted corolla. The anatomy does not support the interpretation that the perianth consists of a six-parted calyx or that the corolla is absent.

The vascular anatomy of the stamen indicates that it has been derived by reduction from a branch system. Vertical compression has resulted in the fusion of the vascular supply of the main limb or rachis of this branch system to the bundles supplying the perianth.

# MORPHOLOGY OF TINOSPORA CORDIFOLIA, WITH SOME OBSERVATIONS ON THE ORIGIN OF THE SINGLE INTEGUMENT, NATURE OF SYNERGIDAE, AND AFFINITIES OF THE MENISPERMACEAE <sup>1</sup>

#### A. C. Joshi

As LITTLE work had been done on the embryology and cytology of the family Menispermaceae prior to 1933, an investigation of some members of this group was started by the writer in that year. During the course of this work an account of the development of pollen was published (Joshi and Rao, 1935), and in 1937 the writer described the structure of the gynoecium and development of the ovule and embryo-sac in Cocculus villosus. In the present paper a similar study has been made of Tinospora cordifolia Miers.

The earlier work on the family was fully summarized in the paper on Cocculus villosus (Joshi, 1937). There is therefore no necessity to recapitulate it here. It is necessary only to mention that since then the writer has come across a small embryological work on Tinospora cordifolia by Abraham (1935), but this is not very critical, and in it several features have been left unobserved by the author.

THE DEVELOPMENT AND STRUCTURE OF THE OVULE.—The gynoecium of Tinospora cordifolia consists of 3-6 free carpels. The most common number is three. Gynoecia with four, five, or six carpels are increasingly rare. These carpels arise from the floral axis in a spiral order, and when the number is more than three, the last carpel is frequently abortive just as in Cocculus villosus (Joshi, 1937).

The mature carpels are always uni-ovulate (fig. 3), but, as in *Cocculus*, two ovules are present in each carpel in the early stages (fig. 1). One ovule <sup>1</sup> Received for publication March 22, 1939.

arises from each of the two margins of the carpels. As the carpellary margins come close together and fuse, the two ovules come to lie nearly in one line, and one of them takes up a position slightly above the other. Both continue to develop equally until the megaspore-mother cell stage (fig. 1). Generally after this, growth suddenly stops in the lower ovule, which is then gradually crushed into an insignificant scaly structure by the developing upper ovule (fig. 2, 3). One can see the beginning of this gradual degeneration of the lower ovule as the tetrad is formed in the upper. By the time the latter reaches the 4-nucleate embryo-sac stage (fig. 2), the lower has completely lost its shape.

This behavior of the ovules in Tinospora, however, is not so constant as in Cocculus. While examining the latter (Joshi, 1937), I found no exception to this condition. In Tinospora, exceptional cases are frequently seen. Figure 5 shows a carpel in which both the ovules have reached the 4-nucleate embryo-sac stage simultaneously. Figure 4 shows a carpel in which the lower ovule has reached the 4-nucleate embryo-sac stage, while the upper is still at the one-nucleate embryo-sac stage. But such variations are of no importance in the end. By the time the mature embryo-sac is formed in the upper ovule, the lower ovule always ceases to grow and is crushed in every case. The general form and structure of the carpel at this stage is shown by figure 3, and no exception to this condition has been observed.

Both ovules after their differentiation from the carpellary margins continue to grow straight till

they meet the dorsal wall of the carpel (fig. 1). Their form up to this stage is perfectly orthotropous. After meeting the opposing carpel wall, the upper ovule turns upward and the lower downward. The functional ovule finally assumes an amphitropous form (fig. 2, 3) under the same influences as act in Cocculus villosus (Joshi, 1937). A small difference is seen only in the post-fertilization stages. In Cocculus, when endosperm develops, there is a marked increase in the size of the funicle, and the ovule becomes campylotropous. In Tinospora, there is no such development of the funicle, and the ovule remains amphitropous throughout its life, though it becomes furrowed on the ventral side due to the development of a longitudinal ridge on the ventral suture of the carpel. This can be seen in transverse sections of a carpel.

The ovule of *Tinospora cordifolia* differs from that of *Cocculus villosus* in the number of integuments. In *Cocculus* (Joshi, 1937), there are two integuments, but there is only one in *Tinospora*. The single integument of *Tinospora*, however, is more massive. In *Cocculus*, both the integuments for their greater length are two to three cells thick. In

Tinospora, the single integument is three cells thick in the micropylar region, but it thickens towards the chalazal end and is here five to six, and for a short distance even more, cells thick. Another point to be noted in the structure of the integument of Tinospora cordifolia is the sudden attenuation in its thickness (generally from five to three cells) on the ventral side just as it becomes free from the nucellus (fig. 2, 3, 7). There is generally a small notch visible here. The difference seen between the structure of the integuments of Tinospora and Cocculus in the mature condition is also present in their initials. This is brought out by comparison of figures 6 and 10. The two initials of the integuments of Cocculus are comparatively slender (fig. 10), while the single integumentary initial of Tinospora is comparatively massive (fig. 6).

The form of the micropyle in *Tinospora cordifolia* is not constant, as may be seen from figures 2 and 3. It may be nearly straight (fig. 2) or, due to greater development of the integument from the dorsal as compared with the ventral side, zig-zag (fig. 3). Between the integument and the nucellus in

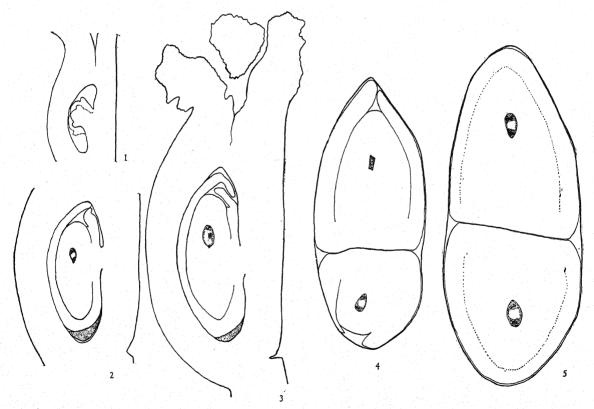

Fig. 1-5.—Fig. 1-3. Tinospora cordifolia. Longitudinal sections of carpels at various stages of development. Fig. 1 shows a carpel with two equally developed ovules at the megaspore-mother cell stage. Fig. 2 shows the lower ovule crushed and the upper at the 4-nucleate embryo-sac stage. Fig. 3 shows the upper ovule at the mature embryo-sac stage, while the lower is still further reduced. ×169.—Fig. 4-5. Tinospora cordifolia. Portions of longitudinal sections of two carpels in which the lower ovule is exceptionally developed. Only the parts to the inside of the inner boundary of the carpel are shown. In fig. 4 the lower ovule shows a 4-nucleate embryo-sac, while the upper is still at the 1-nucleate embryo-sac stage. In fig. 5 both the ovules are at the 4-nucleate embryo-sac stage. Where the boundary between the integument and the nucellus is indistinct, it is shown by dotted lines. ×359.

Micropylar part of the ovule shown in fig. 2 at a higher magnification and showing cellular structure.—Fig. 8. A mature embryosac showing besides the normal features an egg-like synergid and a 2-nucleate antipodal.—Fig. 9. Antipodals from a mature embryo-sac at a higher magnification showing their nuclei in prophase.—Fig. 10. Cocculus villosus. Part of a longitudinal section of an ovule at the megaspore-mother cell stage showing the structure of the nucellus and integuments. Fig. 6, ×910; fig. 7, ×546; fig. 8, ×1740; fig. 9, ×3520; fig. 10, ×910.

the micropylar region of the ovule there is generally present a small air-space (fig. 2, 3, 7).

Another point about the ovule of Tinospora cordifolia which seems to be of some morphological importance is its spatial relations with the inside of the carpel. Going through the series of sections, one always sees in Tinospora the closeness with which the ovule fits inside the ovary. Air-spaces are nearly absent. Only a small one is seen near the micropyle of the ovule (fig. 3), and in the early stages another may be present at the opposite end (fig. 2). At other points the carpel and the ovule so press each other that even the boundaries between them are not very distinct. In Cocculus, there are airspaces between the two integuments and between the inner integument and the nucellus (fig. 13). There are no such air-spaces in Tinospora. This closely pressed condition of the ovule inside the carpel in Tinospora is still further emphasized in carpels where two ovules continue to develop equally even after the megaspore-mother cell stage. In such cases even the small air-space that is seen in the

micropylar region of the ovules tends to disappear (fig. 4) or disappears completely (fig. 5), and the boundary between the integument and the nucellus tends to become partially or completely indistinct. There is thus no clear line in figure 5 between the integument and the nucellus. It is therefore shown in the figure only by dots.

As the spatial relations of the ovule and the carpel in *Tinospora* are of considerable importance in indicating the cause of the origin of the single integument and naked (integument-less) ovules, photomicrographs of sections from which figures 3 and 5 were drawn are presented in figures 11 and 12. For the sake of comparison, a similar photomicrograph of a carpel of *Cocculus villosus* is shown in figure 13. These clearly demonstrate the points described above.

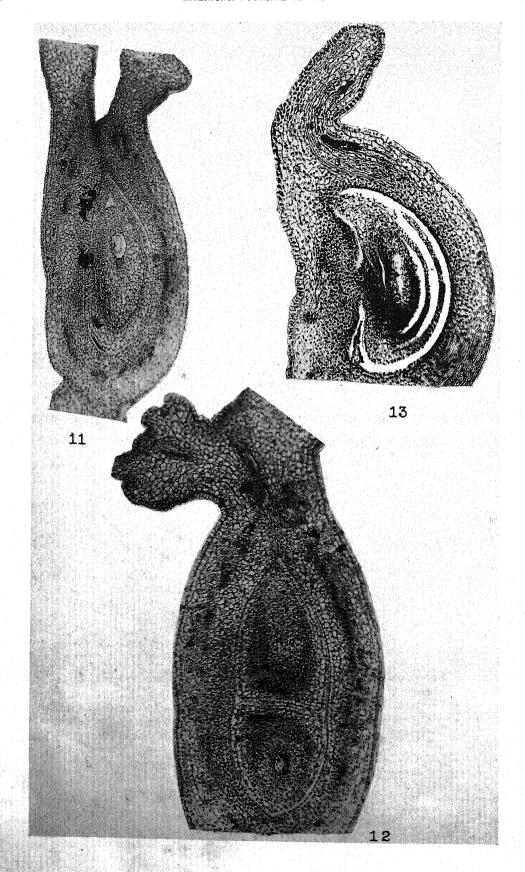

The structure of the nucellus in *Tinospora* is similar to that of *Cocculus* (Joshi, 1937), except that it is slightly better developed. There is a similar cap formation by periclinal divisions in the epidermis (fig. 6, 7). The parietal tissue is more developed than in *Cocculus*. Consequently the embryo-sac in *Tinospora* is deep-seated, and about 15 layers of cells cover it (fig. 7).

THE DEVELOPMENT AND STRUCTURE OF THE EMBRYO-SAC.—The development of the embryo-sac in Tinospora cordifolia is similar to that of Cocculus villosus (Joshi, 1937) and corresponds to the normal type. There is a single hypodermal archesporial cell, which cuts off a primary wall cell. The megaspore-mother cell gives rise to a linear or occasionally T-shaped tetrad of megaspores out of which the chalazal megaspore develops into the 8-nucleate embryo-sac by three free nuclear divisions.

The mature embryo-sac is about  $100 \mu$  long, as in Cocculus, but is slightly different in shape, being broader in the middle (fig. 8). Only two points in its structure require notice here. The synergidae in most cases are quite normal in structure, but occasionally they are egg-like (fig. 8, upper synergid), showing cytoplasm and nucleus at the chalazal end and the large vacuole toward the micropylar end.

The second point refers to the antipodals. The nuclei of the antipodals as these cells are organized are in the resting condition, and they show this condition in young 8-nucleate embryo-sacs. After the polar nuclei have fused, the nuclei of the antipodals prepare to divide. They enter the prophase stage (fig. 9), but generally the division is not completed, and they remain in this condition until the disorganization of antipodals. In a few cases, however, these nuclei have been seen to divide completely, and some antipodal cells become 2-nucleate (fig. 8, the left hand upper antipodal).

Discussion.—Origin of the single integument.— The embryological characters of Tinospora cordifolia closely resembles those of Cocculus villosus described previously (Joshi, 1937) except in the form of the ovule and the number of integuments. In Cocculus villosus the ovules are amphitropous up to the

embryo-sac stage but become campylotropous afterward. In Tinospora cordifolia they are amphitropous throughout their life. The number of integuments is two in Cocculus villosus, while the ovules of Tinospora cordifolia possess only one integument. In showing this difference between closely related plants, the family Menispermaceae agrees with families like Ranunculaceae, Rosaceae, and Leguminosae (Schnarf, 1931). Such groups are interesting morphologically, because from comparison of closely related forms some light can be thrown on the origin of the single integument.

Because the primitive Archichlamydeous families among the Dicotyledons mostly show two integuments and the single integument of the Metachlamydeous Dicotyledons is in general as massive or even more massive than both the integuments when there are two, Coulter and Chamberlain (1903) long ago expressed the opinion that the single integument "represents two integuments in the sense that their primordia are no longer differentiated." This generally accepted view needs a little modification in the case of Tinospora cordifolia. Comparison of this species with Cocculus villosus shows that the single integument of the former in the chalazal part is nearly as massive as both the integuments of the latter put together. A similar difference is seen in the primordia of the integuments in the two genera. There is therefore no doubt that in the chalazal part of the ovule the single integument of Tinospora has resulted from the fusion of two integuments like those of Cocculus, but a different interpretation is necessary for the micropylar part of the integument. In this region the integument is only as thick as the single integument of Cocculus. Further, just as it separates from the nucellus, it shows a small notch on the ventral side. At this point it undergoes a somewhat sudden decrease in thickness, and it appears as if the former inner integument is coming to an end. For these reasons the single integument of Tinospora in the micropylar part of the ovule is equivalent only to the outer integument of Cocculus.

Very little is known as present about the probable cause of the origin of the single integument from two. On this point also a comparison of the carpels and ovules of Tinospora and Cocculus throws some light. Such comparison shows that there is only one difference between the two plants that can account for the replacement of two integuments by one, and that is the larger size of the ovule as compared with the ovary in Tinospora. This leads to the closely pressed condition of the ovule inside the carpel and the obliteration of most of the air-spaces. It can be reasonably suggested that the mechanical pressure which is thus exerted on the ovule during its development may have been the primary cause of the replacement of two integuments by

one, by selecting variations in this direction. A careful comparison of other closely related plants, such as species of *Delphinium* and other Ranunculaceae, which are known to differ in the number of integuments should throw more light on this subject.

An extension of the above hypothesis can also indicate the method by which naked (integumentless) ovules, which are found in a few flowering plants,<sup>2</sup> could have originated in some cases. We see in Tinospora, when two ovules in a carpel continue to develop equally even after the megaspore-mother cell stage, the boundaries between the different parts tend to become indistinct as a result of the extra mechanical pressure to which they are subjected. There is thus in figures 5 and 12 no clear line between the nucellus and the integument. The integument can be distinguished only by the different form of its cells. If these cells were similar to those of the nucellus, no difference would be visible between the two, and the ovule would be described as naked. The naked ovules such as have been described in the saprophytic Gentianaceae Leiphaimos and Cotylanthera by Oehler (1927) appear to have developed in this manner. This is clear from the orientation of their embryo-sac.3

Morphology of the synergidae and embryo-sac.— The synergidae differ from the egg cell in their vacuolation and the position of cytoplasm and nucleus. The egg has a large vacuole toward the micropylar end, while the cytoplasm and the nucleus are pressed toward the chalazal end. In the synergidae the position of these parts is just the reverse. The vacuole is found toward the chalazal end, while the nucleus and cytoplasm occupy the micropylar end.

<sup>2</sup> According to Wettstein (1935), naked ovules occur in Santalaceae, Loranthaceae, Balanophoraceae, Olacaceae, saprophytic Gentianaceae, and species of *Crinum*. To this list may be added the genus *Houstonia* of the Rubiaceae (Lloyd, 1902).

3 Maheshwari (1937) in his recent review of the embryo-sac of angiosperms, while dealing with the reversed polarity of the embryo-sac, remarks that the saprophytic Gentianaceae like Leiphaimos and Cotylanthera, the Loranthaceae, and the Balanophoraceae provide the best instances of reversed polarity of the embryo-sac. This would be so if the ovules of these plants were really orthotropous. In these saprophytic Gentianaceae, however, it is clear that they are not so. They are only apparently orthotropous. Actually they are anatropous, and the embryosac is quite normally orientated. The families Loranthaceae and Balanophoraceae are highly specialized, and the morphology of the ovule in these families is not very clear. To describe their embryo-sac as reversely orientated in the light of our present knowledge is unjustified. In dealing with the reversed polarity of the embryo-sac, it is better to leave such examples alone. Perhaps it would be better to interpret the morphology of the ovule in these families by a study of the orientation of the embryo-sac. In the writer's opinion, complete reversed polarity of the embryo-sac is not the normal character of any angiosperm. It always occurs as a rare abnormality, and the case of Woodfordia floribunda described by Joshi and Venkateswarlu (1935) is a good illustration of this.

Fig. 11-13.—Fig. 11. Tinospora cordifolia. Longitudinal section of a normal carpel with the ovule at the mature embryo-sac stage.  $\times 60$ .—Fig. 12. Tinospora cordifolia. Longitudinal section of a carpel with the ovule showing mature embryo-sac.  $\times 120$ .

The synergidae of Tinospora cordifolia are interesting in showing occasionally egg-like structurei.e., vacuole toward the micropylar end and cytoplasm and nucleus toward the chalazal end. Similar egg-like synergidae have been observed in Iris sibirica (Dodel, 1891), Aconitum napellus (Osterwalder, 1898), Trillium grandiflorum (Ernst, 1902), Mercurialis annua (Malte, 1910), Myricaria germanica (Frisendahl, 1912), Delphinium elatum (Persidsky, 1914), and Fritillaria pudica (Sax, 1916). They have also been described by Svensson (1925) in Nemophila atomaria, by Puri (1934-1935) in Moringa oleifera, and Johri (1936) in Sagittaria graminea. During the course of the embryological investigations carried out in this department in recent years, synergidae with egg-like structure have been found in Gisekia pharnaceoides (Joshi and Rao, 1936), Tamarix dioica (Joshi and Kajale, 1936), Boerhaavia diffusa and B. repanda (Kajale, 1938), Clerodendron Phlomidis (Misra, 1939), and several Amarantaceae and Bergia ammanioides (Kajale, unpublished). As these examples are from plants which come from different families, it is very likely that future research may reveal many more instances, since egg-like synergidae are not a rarity, as might have been supposed a few years ago.

Development of embryos from synergidae has been seen in Mimosa Denhartii (Guignard, 1881), Orchis morio (Strasburger, 1886), Iris sibirica (Dodel, 1891), Lilium martagon (Overton, 1891), Aconitum napellus (Osterwalder, 1898), Najas major (Guignard, 1901), Trillium grandiflorum (Ernst, 1902), Delphinium elatum (Persidsky, 1914), Hypericum maculatum (Schnarf, 1914), Gastrodia elata (Kusano, 1915), Fritillaria pudica (Sax, 1916), Sagittaria graminea (Johri, 1936), and Boerhaavia repanda (Kajale, 1938), and it appears that in many of these cases it is due to the fertilization of egg-like synergidae. The synergidae therefore do not differ fundamentally from the egg and should be regarded as of the same nature.

With reference to the morphology of the angiospermous embryo-sac, we find, as Maheshwari (1937) has recently summarized, three chief views. According to Porsch (1907), the 8-nucleate embryosac of angiosperms is equivalent to two archegonia without any prothallial tissue. The synergidae, egg, and the upper polar nucleus form one archegonium, -the synergidae being equivalent to neck cells and the upper polar nucleus to the ventral canal nucleus,—while the three antipodals and the lower polar nucleus form the second but now functionless archegonium. According to Schürhoff (1928), one synergid (= a ventral canal nucleus) and the egg constitute one archegonium, the second synergid and the upper polar nucleus constitute a second archegonium, while the antipodals and the lower polar nucleus are prothallial. According to the third view, all the nuclei of the embryo-sac are potential eggs, although only one of them produces an embryo. The previous observations on the na-

ture of the synergidae support the last view about the morphology of the embryo-sac. This is further supported by the occasional occurrence of egg-like antipodals and even their fertilization, as in *Ulmus americana* (Shattuck, 1905), and rarely by the reversal of the polarity of the whole embryo-sac, as in *Lawsonia inermis* (Joshi and Venkateswarlu, 1935)

Affinities of the Menispermaceae.—At present it is generally maintained that the family Menispermaceae is related to the Magnoliaceae and Ranunculaceae alliance and can be placed definitely in the order Ranales of Bentham and Hooker (1862-1883) or Engler and Gilg (1924), or Polycarpicae of Wettstein (1935). Within the Ranales or the Polycarpicae, however, there are two distinct views about its affinities. Wettstein, on account of the woody habit of its members and the occurrence of secretory cells in the parenchymatous tissue of the vegetative parts, believes that it is more closely related to the Magnoliaceae and allied woody families. Hutchinson (1926), on the other hand, although he attaches even greater importance to habit of the plants in his classification of the dicotyledons, thinks that the Menispermaceae are more nearly related to the Ranunculaceae. We can now discuss what light embryological evidence throws on this question.

The development of the embryo-sac both in the Ranunculaceae and Magnoliaceae is very similar, but there are a few other features which appear to be of some value for our study. In all the Magnoliaceae investigated so far the number of integuments is constantly two, while it is variable in the Ranunculaceae. The Menispermaceae thus agrees with the Ranunculaceae. The antipodals of the Menispermaceae in showing the tendency to divide resemble more those of the Ranunculaceae (Huss, 1906) than the small, often early degenerating antipodals of the Magnoliaceae (Schnarf, 1931). Finally, there is one characteristic feature of the pollen grains of Tinospora which appears to be of great significance in this connection. This is the fringed margin of the germ pore (Joshi and Rao, 1935). Pollen grains with fringed margin of the germ pores are found in the monocotyledonous families Alismataceae, Butomaceae, and Hydrocharitaceae (Wodehouse, 1936b), but among the dicotyledons they are found only in the Ranunculaceae (Wodehouse, 1936a). Although the pollen of a number of Magnoliaceae has been studied (Wodehouse, 1935), grains with fringed margin of the germ pores have not been found in any case. The evidence from the present studies, therefore, is in favor of placing the Menispermaceae with the Ranunculaceae as suggested by Hutchinson (1926).

#### SUMMARY

The gynoecium of Tinospora cordifolia consists of 3-6 spirally arranged carpels. When the num-

ber is more than three, the last carpel is frequently abortive. Two ovules differentiate at first in each carpel, but later the lower is suppressed. The functional ovule is amphitropous, has only one integument, and is closely pressed inside the carpel. The nucellus shows an epidermal cap. The development of the embryo-sac is quite normal. The synergidae frequently show egg-like structure. The nuclei of the antipodals show a tendency toward division.

The single integument appears to have resulted from the fusion of two in the chalazal and suppression of the inner in the micropylar part. The synergidae are of the same nature as the egg. The family Menispermaceae is more closely related to the Ranunculaceae than to the Magnoliaceae.

# CAULOXYLON AMBIGUUM, GEN. ET SP. NOV., A NEW FOSSIL PLANT FROM THE REED SPRINGS FORMATION OF SOUTHWESTERN MISSOURI <sup>1</sup>

J. E. Cribbs

THE PETRIFIED stem described in this paper was found in Greene County, Missouri, and was given to E. L. Clark, professor of geology at Drury College, who referred it to the writer for identification.

It was picked up from an accumulation of chert in a small ravine, and, although not embedded when found, it is assumed to have been included in a chert matrix which fractured and broke up under the influence of weathering. Since this chert has been ascribed to the upper part of the Reed Springs Formation, the plant probably lived during the earlier half of Mississippian time.

STATE OF PRESERVATION.—The portion of stem found is about 15 cm. long, 7.5 cm. wide, and 5.5 cm. thick. It is straight and without branches or appendages other than leaves which are represented

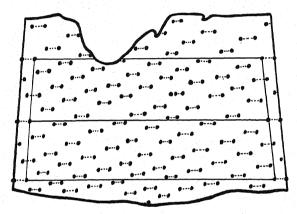

Fig. 1. A flat projection of the stem surface, showing the distribution of leaf traces as they entered the cortex. Paired traces are connected with broken lines. Three superposed nodes of the same orthostichy are shown at the left and repeated at the right.  $\times 5/14$ .

by traces in the secondary wood. The elliptical outline as seen in transverse section (fig. 18) is due to compression. All structures external to the secondary wood are lost, and the latter may not be complete. The pith, primary wood, secondary wood, and leaf trace bundles are preserved and infiltrated with siliceous materials. There is evidence that the stem was bruised and buffeted about before fossilization took place, a fate common to stems carried out to sea by rivers or derived from eroding shores. The obscure condition of pits on the walls of primary and secondary tracheids is probably due to partial decay before petrifaction. Throughout all tissues there is an extensive development of spherulites which in many places obscure the structural features and make observation difficult.

Phyllotaxis.—Regularly arranged on the surface of the stem are many small protrusions which sections prove to be convoluted knots of tracheids developed opposite the terminus of leaf trace bundles. Since these are visible on all of the surface area (fig. 19), the phyllotaxis could readily be determined.

A flat projection of the stem exterior drawn to scale with the distribution of outgoing leaf traces is shown in figure 1. The traces originate and pass out through the secondary wood in pairs. One bundle (that in the anodic position) is slightly higher than the other where it enters the secondary wood from the pith. The two bundles of a pair are shown connected by a broken line in the figure. Three successive nodes of an orthostichy are shown at the left, and the same three appear again at the right side. Between the lower and middle horizontal lines lie all the paired traces which intervene between the first and second nodes of the orthostichy. The ascending spiral is toward the right, and the thirtyfourth node lies directly over the first in series. Between the middle and upper horizontal lines there is the same arrangement. The apparent spirals toward the right are parastichies. Each successive node in the true spiral occurs in the third parastichy to the right of the preceding one, thus the spiral passes around the stem twenty times to reach the thirty-fourth node above, and the phyllotaxis may be represented by the fraction 20/34.

One irregularity to be observed in the trace arrangement is shown in the figure at the fourteenth node of the second series, where three traces emerge at the surface instead of two. All three lie on a horizontal plane. From the grouping of the traces, it is apparent that they should be interpreted as pairs which continued into the cortex with or without further division before they entered the petioles. It will be observed that the vertical spacing is different toward the two ends of the stem, being greater distally. The average distance between two successive nodes of the same orthostichy is about 4.5 cm., which gives an average internodal distance of 1.3 mm.

PITH.—In transverse section (fig. 18), the pith as preserved is 52 mm. wide and 32 mm. thick. It is therefore of unusually large size. There is no indication of septa such as characterize the large pith of most stems referred to as Cordaites. It is continuous throughout and has scattered within it numerous "sclerotic nests" which occur at irregular intervals. On the exposed surface of the pith at the proximal end, forty-two such nests are visible. In a transverse section about 2.5 cm. higher the number observed is considerably less. This may have no sig-

<sup>&</sup>lt;sup>1</sup> Received for publication April 24, 1939.

nificance since the number is variable in the serial sections cut from a portion of the stem. Although nests occur throughout the central region of the pith, they are absent in an outer zone of 3-5 mm. width adjacent to the secondary wood. Most sclerotic nests are approximately spherical in shape, and are composed of a group of polyhedral cells surrounding which the adjacent pith cells are elongated and so disposed as to form a conspicuous radial pattern as viewed in any sectional plane (fig. 10, 20). They vary from .1 mm. to 1 mm. in diameter (average .4 mm.). In most of them the central cells are not preserved except immediately adjacent to the pith and the central area may be more or less filled with brick-red granules which may represent decomposition products or resinous materials originally contained in the central mass. Commonly the central cavity is filled with calcite crystals.

In most sections the nests appear with greater frequency about 4 mm. from the secondary wood where they mark a fairly definite boundary between two pith zones (fig. 3)—a large central area where the cells as seen in transverse section are approximately equal in tangential and radial dimensions and a marginal zone where the pith cells are elongated radially. This elongation is particularly conspicuous between sclerotic nests and the secondary wood, between neighboring nests, and between marginal nests and nearby primary strands. The prominently elongated pith cells are relatively narrow and are darker than adjoining cells, which is apparently due to the presence of more organic matter. Such an arrangement and appearance suggest a primitive adaptation for conveying materials and indicate that the sclerotic nests may have been
